Two suggestions may be made. The compound may prevent the destruction of a vasoconstrictor amine at the site of implantation, thus preventing vascular changes essential for this process to be completed[1]. Alternatively, it may stimulate hormonal secretion in the pituitary-suprarenal axis of a nature unfavourable to the establishment of pregnancy. Such stimulation could be direct or indirect through the mediation of pressor amines.

Reversibility of an Inherited Metabolic Block (Inborn Error of Metabolism)

The irreversibility and permanence of the basic defects in 'inborn errors of metabolism' have been regarded hitherto as essential pre-requisites of the condition as defined by Garrod[1]. The question is whether in the light of the following observations this aspect of Garrod's concept can yet be universally maintained.

We have had the opportunity of observing two siblings with sporadic goitrous cretinism, which condition is known to arise from a genetically transmitted failure of thyroid hormone synthesis[2]. In our cases the metabolic block was found to be an inability of the thyroid to hold inorganic iodide and convert it to organic iodine (abnormally high uptake of iodine-131 during the first hours after the administration of the tracer, with a subsequent drop to abnormally low levels, low serum-protein-bound iodine-127; see Table 1). The resulting clinical manifestations were in both siblings a large, partly diffuse and partly nodular goitre, and severe myxœdema. The short-termed administration of massive doses of active thyroid principles (90 mgm. 'Triac' or equivalent doses of desiccated thyroid within 6–9 days) resulted each time in a protracted clinical remission lasting without additional therapy 6–7 months (altogether this 'stosstherapy' was performed five times). Studies of thyroid function performed at 2, 3 and 4 months of the therapy-free remissions revealed a practically normal pattern of thyroid function, thus incidentally also ruling out a fortuitious ingestion of thyroid substances[3,4].

In a third sibling, who only recently came under our observation and who was clinically and functionally perfectly like those previously studied, the same therapeutic procedure also resulted in a protracted and complete clinical remission which so far lasts 8 months. Thyroid function studies performed at early stages of the therapy-free remission revealed a low-normal pattern. The most striking and unexpected result of isotope studies was obtained at almost 6 months after the administration of the 'Triac stoss' (Table 1). The figures show that the thyroid gland which, according to universally accepted views must be the site of an inherited metabolic block at an early stage of hormone synthesis, was by that time not only capable of holding abnormally large amounts of iodine (6 days after the administration of the tracer, thyroidal collection was still 41 per cent) but also of converting it at a high rate to organic-bound iodine. That at least part of the protein-bound iodine released into the circulation was biologically active may be inferred from the clinical state of the patient, who was both euthyroid and agoitrous. Chromatographic study of the circulating iodine compounds could unfortunately not be undertaken, as the dose of iodine-131 administered was too small for this purpose. It will be the subject of further investigations.

This is, to the best of our knowledge, the first time that a genetically transmitted, that is, inborn, error of metabolism was at least temporarily repaired and converted into normal metabolic channels functioning at a higher rate even than normal. It is worthy of note that this effect was achieved by the extraneous administration of massive doses of sub-

Effect of Wheat Gluten on the Peristaltic Reflex

SENSITIVITY to wheat or rye gluten is the essential mechanism in the pathogenesis of cœliac disease and idiopathic steatorrhœa. Such patients improve on a gluten-free diet and deteriorate on the re-introduction of gluten itself or its autoclaved and filtered peptic/tryptic digest into the diet[1]. In these diseases a disturbance of small intestinal function is a major factor[2].

The peristaltic reflex of the isolated intestine[3] was used to test the depressant activity of gluten and several of its fractions on intestinal motility. Perfusion of the autoclaved and filtered peptic/tryptic digest through the lumen did not produce any depression of this preparation. External administration, however, caused complete inhibition of longitudinal as well as circular muscle contraction. Movements returned while the material was still in the bath. This depression was also shown by an aqueous extract of gluten and was not affected by ultrafiltration. The ultrafiltrate of the aqueous extract was ten times as potent as the peptic/tryptic digest. All activity was abolished by acid hydrolysis. Incubation of the active material for a few minutes with small intestinal mucosa from the rat and with one specimen of human jejunal mucosa abolished the inhibitory effect.

The mechanism of this depressant effect of gluten fractions was studied with the help of the co-axially stimulated isolated guinea pig intestine[4]. The twitch response was markedly depressed for several minutes with either fraction. Assay of the acetylcholine output on the isolated guinea pig ileum treated with neostigmine and morphine[4] showed a significant depression with the addition of either material. In preliminary experiments, the synthesis of acetylcholine by small intestinal cholinacetylase[5] was not affected by the addition of the ultrafiltrate of the aqueous extract of gluten.

The conclusion is drawn that wheat gluten which is pathogenic in cœliac disease and idiopathic steatorrhœa contains a factor which depresses the peristaltic reflex of an isolated strip of intestine. This factor is heat-stable, resistant to peptic/tryptic digestion and not removed by ultrafiltration. It is sensitive to acid hydrolysis and digestion with small intestinal mucosa. It depresses acetylcholine output, but synthesis does not appear to be affected at moderate dosage-levels. It may therefore prevent release of acetylcholine from the inactive bound state.

HÆMATOLOGY

Substance from Erythrocytes of Blood Group A

BLOOD group substances from erythrocytes have been claimed to be glycolipids, while those from secretions were described as mucopolysaccharides. It has been suggested that glycolipids from erythrocytes owe their blood group activity to the contamination by secretions like blood group substances[1]. The problem of identity or relationship between these two kinds of blood group substances may be solved only if their chemical and serological properties are directly compared.

The present communication describes the isolation and properties of a human blood group A substance from erythrocytes. Determinations of isoagglutination inhibition and hæmolysis (Forssman) inhibition tests were made using as a control the original sample of blood group A substance (kindly given by Prof. W. T. J. Morgan and Dr. W. M. Watkins of the Lister Institute, London) hereafter referred to as a 'standard A substance'.

Pooled, washed, human A erythrocytes were extracted with 4·05 vol. of 96 per cent w/w ethanol for 24 hr. at room temperature. The extract was Seitz-filtered and cooled to −7° C. A precipitate, 'crude A substance', which formed was centrifuged at −7° C., washed with acetone and dried in a vacuum. Its blood group activity, as measured by the isoagglutination inhibition test, was 2–5 per cent of the activity of the standard A substance; it did not contain O, H, Rh, M, N, P factors and exhibited no influenza virus hæmagglutination inhibition activity. Chemical analysis revealed 15·5 per cent reducing sugars as galactose, 2·6 per cent hexosamine, 3·4 per cent phosphorus, 2·0 per cent nitrogen; the glucosamine/galactosamine ratio[2] was 1 : 4.

The crude substance was extracted with acetone, ethyl ether, and petroleum ether successively, then dissolved in boiling methanol, filtered while hot, and the extract was cooled to 0° C. The precipitate formed ('precipitate M') contained 26·3 per cent reducing sugar, 5·0 per cent hexosamine, 1·4 per cent phosphorus. Its activity was about 10 per cent of that of the standard substance.

A sample of 'precipitate M' has been further purified by chromatography on a cellulose column. Two fractions emerged from the column: fraction I in

Table 1. CHEMICAL COMPOSITION OF A PREPARATIONS

Fraction I	—	—	4·82	26·0	—	1·4	5	25
Fraction II	2·3	1·4	9·4	47·6	1 : 1	0·3	25	100

* Expressed as percentage of the activity of standard A substance.

chloroform/ethanol/water, 16 : 4 : 1, and fraction II in chloroform/methanol/water, 5 : 15 : 1. They represented about 90 and 5 per cent of the chromatographed material, respectively. The properties of the two fractions are shown in Table 1. Fraction II was soluble in both water and organic solvents (pyridine, hot methanol, mixtures of chloroform and methanol). In water it forms a somewhat opalescent solution, exhibiting a considerable viscosity. This substance gave no reaction with *p*-dimethylaminobenzaldehyde described by Aminoff, Morgan and Watkins[3]. Galactose, glucosamine and galactosamine were identified in this material by means of paper chromatography in butanol/pyridine/water solvent. Fucose content of this material was 0·8–2·0 per cent. Fraction II may be further purified by extracting it with a large volume of hot 95 per cent acetone, then by cold precipitation from hot methanolic solution and finally by pyridine extraction and absorption on alumina, essentially after the method of Klenk and Lauenstein[4]. One of our best preparations obtained by the above methods contained 16·6 per cent hexosamine, 60 per cent reducing sugars, 2·7 per cent nitrogen and 1·37 per cent sphingosine nitrogen[5]. The sum of sphingosine and hexosamine nitrogen represented 98·8 per cent of the total nitrogen. The galactosamine/glucosamine ratio was 6 : 1[2]. Analytical values suggest that this material is hexosamine-sphingosine-trihexoside somewhat similar to preparations of red cell blood group substances described by Yamakawa and Suzuki[6]. The preparation was not tested for homogeneity, but fraction II did display two hexosamine-containing components in fractional solubility tests with methanol; the percentage ratio of the components amounted to 78 and 22 per cent. The activity of fraction II was about 12·5 per cent of the activity of standard substance. However, with a small number of anti-A sera, the erythrocyte substance was 10–20 times as active as standard A substance, but both appeared to be less active when tested against these particular sera than against the usual ones. The possibility cannot be excluded that these sera contained some unknown antibody against other components of the erythrocyte surface. The hæmagglutination inhibition activity has also been tested by Prof. W. T. J. Morgan against various anti-A reagents. Substances obtained from erythrocytes when tested against rabbit anti-human red cells sera were active in dilution of about 10^5, while when tested against rabbit anti-mucoid A substance sera showed activity of a lower order (about 10^4).

It is interesting to note that neither substances obtained from A red cells nor from O red cells contained O or H antigen.

The blood group activity of our preparations was not destroyed by treatment with hot 0·05 *N* sodium carbonate for 15 min., and no N-acetylhexosamine colour has developed on subsequent treatment with Ehrlich reagent[3]. This is exactly opposite to what has been found with substances obtained from body fluids[7]. When the erythrocyte substance was treated with hot hydrochloric acid, *p*H 2·3, for 8 hr. the kinetics of both disappearance of activity and appearance of N-acetylhexosamine colour were similar to those found for the mucoid A substance.

The above results point to the fact that blood group substance as obtained from human erythrocytes is a different chemical entity from the blood group substance as obtained from human body fluids.

Haptoglobin Types in 398 Blood Donors from Dakar (Senegal)

FROM results already published on the haptoglobin types in African populations, three points deserve attention. First, the Hp (1–1) type is very frequent. Secondly, the Hp (1–2) modified type, described by Connel and Smithies, is present much more often than in European populations[1]. Thirdly, the so-called ahaptoglobinæmic sera, which are so rare in the latter, were found in Africa with a frequency of up to 40 per cent[1,2].

In the present work, we have studied 398 serum samples from blood donors registered at the Centre Fédéral de Transfusion Sanguine, Dakar. The technique of electrophoresis in starch gel was that previously used by us[3], in a borate buffer at *p*H 8·3. In addition, a control in a phosphate buffer at *p*H 7·0 (ref. 4) was made on all the samples in which the characteristic bands of the Hp (1–2) or Hp (2–2) types were missing. It was thus very easy to distinguish the so-called ahaptoglobinæmic sera from those belonging to the Hp (1–1) type.

The observed frequencies are:

Hp (1–1)	148	(37·19 per cent)
Hp (1–2) normal	141	(35·43 per cent)
Hp (1–2) modified	44	(11·05 per cent)
Hp (2–2)	47	(11·81 per cent)
Special types	2	(0·50 per cent)
No haptoglobin detectable	16	(4·02 per cent)

The proportion of the sera in which no haptoglobin was detectable is very much lower in our results than that obtained by Allison *et al.*[2] and by Harris *et al.*[1]. In Gambia, Harris *et al.* found more than 40 per cent of such sera. On the other hand, Sutton *et al.*[4] did not specially seek the ahaptoglobinæmic types, but their figures suggest a low frequency, of the same order of magnitude as ours.

Sera which were weakly stained by the benzidine reagent were very frequent in the material we tested. Presumably, minor differences in the technique could have led us to classify them in the 'ahaptoglobinaemia' group. In such populations, if the size of this group is so largely dependent on the technique, it will be very difficult to make accurate comparisons from an anthropological point of view.

A more detailed report will be given elsewhere[6].

BIOLOGY

Translocation of Wild Animals as a Means of Game Control

A preliminary trial in the translocation of the herd of kob antelope (*Adenota kob thomasi*) at Lugari in Kenya was made in June of last year (Buechner, H. K., Harthoorn, A. M., and Luck, C. P., unpublished work). The herd in question numbers some 500 head, and is the only herd of kob in Kenya. Its existence in this number on the farm- and ranch-land of Lugari cannot be supported by the landowners. Moving part of the herd to other areas is the only alternative to destruction.

During the first eight days of the scheme early in March of this year, forty animals were darted, using one Capchur gun and Crockford syringes. Of this number 13 failed to go down; this was discovered to be due to a fault in loading, with resulting syringe blow-out between leaving the gun and entering the animal; three animals escaped on the first day due to faulty construction of the holding area; and three animals died during immobilization. Whereas deaths due to succinylcholine had not been reported previously in the course of immobilizing some sixty males, it appears that the female, possibly only the pregnant female, is more susceptible. After adding atropine to our succinylcholine solution, as is our routine practice with animals such as buffalo, no more deaths from this cause ensued. Among the first animals caught, two died from injuries caused by their efforts to break out of the stockade. Adequate thatching of the inner face of the perimeter stockade will possibly prevent this in the future, as will the presence of tame animals. Furthermore, these animals had not been tranquillized with 'Largactil'.

Twenty kob were ready at the end of the eight days for loading on to a truck to be moved to a game reserve 320 miles away. Of these, 18 were females, the greater number of whom were clearly pregnant; two were sub-adult males. The extreme tips of the young horns of the males were removed and the ends covered with strips of 'Elastoplast'. They were caught one by one by being driven into a crush, injected with 'Largactil' (chlorpromazine hydrochloride) and placed in the darkened truck interior. There they settled down immediately. The inner walls of the lorry had also been lined with grass.

The first attempt at moving these animals from the holding enclosure failed. The crush at that time opened into a small catching chamber where it was hoped to hold the animal by manual restraint while the injection was being made. This proved to be quite impracticable, and some injury was inflicted on the handlers. A modification whereby the animals ran through the crush into a specially constructed slatted box, where they could be tranquillized and afterwards moved to the truck, proved to be satisfactory. It was found convenient to drive the animals into the crush at dusk. Artificial lights were used to encourage the animal to move towards the slatted box. The animals were transported during the night to avoid overheating—an important factor in tropical climates.

In the first batch moved there were a dozen females and one male. All arrived safely at the new Meru Game Reserve, having travelled a distance of 320 miles.

The trial has indicated that the number of animals that can be caught by one gun or other projector, and moved per week, can be at least doubled with increased experience and improved equipment. This method of game control has now been shown possible. It is hoped that the principle of removing wild animals from contested areas will be used with increasing frequency instead of the destruction that has been practised up to date.

We wish to express our gratitude to the farmers in the Lugari area for their co-operation with us on this scheme. Equipment was supplied by the Kenya Game Department and the project has been assisted by a grant-in-aid from the Fauna Preservation Society, London. The succinylcholine chloride was kindly given by Messrs. Burroughs Wellcome (East Africa), Ltd., and the 'Largactil' by Messrs. May and Baker.

Effect of Penicillin on the Maintenance of Rumen Oligotrich Protozoa

It has been shown previously[1,2] that sheep rumen *Entodinia* spp., principally *Entodinium caudatum*, could be grown *in vitro*, dividing every 48 hr. on a medium of salts, dried grass, rice starch, chloramphenicol and fresh or autoclaved rumen fluid, but that it was necessary to add fresh grass and rice starch to the medium every day. This communication describes the successful maintenance of these Protozoa in the presence of penicillin for periods up to 14 days without daily additions.

The substrate consisted of 3–4 ml. quantities of mineral salt solution *B* (see below) plus about 6 mgm. dried grass[1] and 0·2 ml. 10 per cent 'Difco' yeast-extract contained in cotton-plugged 7-ml. tubes (fitted with ground glass stoppers) and autoclaved at 10 lb./sq. in. for 20 min. Immediately after removal from the autoclave and cooling, the following additions were made aseptically: 0·2 ml. 1 per cent L-cysteine hydrochloride (neutralized with sodium hydroxide and Seitz-filtered just before use), 0·2 ml. 5 per cent sodium bicarbonate (Seitz-filtered), 0·25 ml. 6 per cent rice starch (British Drug Houses, Ltd., Poole, England; heated at 120° for 24 hr.), 0·8 ml. Protozoa-containing autoclaved rumen fluid and 0·4 ml. 25,000 U. penicillin *G*/ml. (sterile). The tubes were then inoculated, completely filled with sterile mineral salt solution *B* and sealed with flamed glass stoppers, taking care to exclude all air. The cultures were incubated at 38° without further additions to the medium. The mineral salt solution *B* contained per 100 ml.: K_2HPO_4, 0·50 gm.; KH_2PO_4, 0·39 gm.; NaCl, 0·050 gm.; $MgSO_4.7H_2O$, 0·007 gm.; $CaCl_2.6H_2O$, 0·007 gm.; CH_3CH_2COONa, 0·375 gm. The Protozoa-containing autoclaved rumen fluid was prepared from the rumen contents of a hay-fed Clun Forest sheep by straining through two layers of muslin and autoclaving under 95 per cent nitrogen + 5 per cent carbon dioxide in sealed McCartney bottles for 20 min. at 10 lb./sq. in.

The Protozoa (more than 90 per cent *Entodinium caudatum*) for inoculation were prepared from cultures which were growing in the presence of rice starch, grass, chloramphenicol and autoclaved rumen fluid under the condition *C2*[2] and which had been last diluted 48 hr. previously. Under these conditions the Protozoa formed a layer at the bottom of the tube, and the grass formed a scum on the surface. This surface scum was removed and then the residual medium plus the Protozoa centrifuged at 400*g* for 1 min. on an angle-head centrifuge, the organisms washed twice on the centrifuge in 10 ml. of sterile mineral salt solution containing 0·03 per cent L-cysteine and inoculated. The initial number of Protozoa was usually 3,000–20,000/ml.

Rough viable counts on the number of bacteria present in the protozoal cultures were made by carrying out serial tenfold dilutions in cotton-plugged test-tubes containing 10-ml. quantities of the following medium: mineral salt solution[1] without the sodium acetate containing 0·5 per cent 'Difco' yeast extract, 0·5 per cent glucose, 0·5 per cent 'Difco Bacto-tryptose', 0·35 per cent sodium lactate and 4·0 per cent Protozoa-containing autoclaved rumen fluid (centrifuged to remove the solid matter), autoclaved at 10 lb./sq. in. for 20 min. The cultures were incubated aerobically at 38° until no further growth was observed (about 4 days); the addition of 0·05 per cent L-cysteine and incubation in anaerobe jars under 95 per cent hydrogen + 5 per cent carbon dioxide (without catalyst) did not increase the number of viable bacteria found in penicillin-treated cultures.

Under the cultural conditions described the number of Protozoa increased for 3–7 days (Fig. 1), and the omission of the yeast extract or Protozoa-containing autoclaved rumen fluid reduced or prevented the growth of the Protozoa although they remained alive for up to 7 days. Similar results with a doubling in the number of Protozoa in 3–7 days were obtained from inocula of 2,000–40,000 Protozoa/ml. and in the best experiments fivefold increases were obtained in 3 days. From the third–seventh day onwards, depending on the experiment, the number of Protozoa declined steadily until they were usually dead by the twelfth–fourteenth day, although some occasionally persisted for 16–17 days.

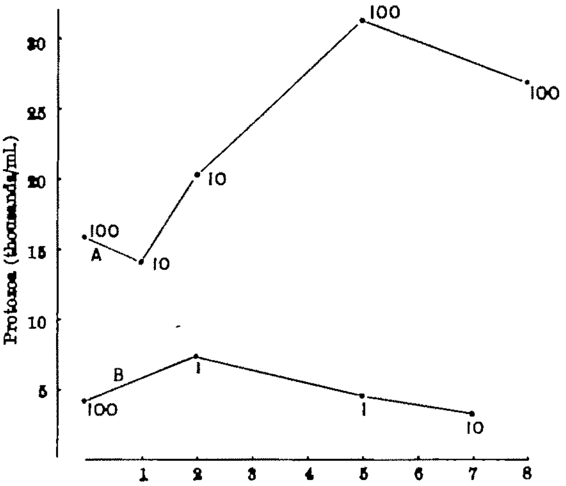

Fig. 1. Maintenance of *Entodinia* spp. in the presence of penicillin, without daily additions, under the conditions described using two levels of inoculum. The figures at each point indicate in thousands the approximate number of bacteria per ml. in the complete culture

Fig. 1 shows that the number of viable bacteria present in the complete protozoal culture containing the Protozoa was 10^3–10^5/ml., but in approximately half the experiments the number of bacteria present during protozoal growth was 10^6–10^7/ml. However, in almost all experiments the rice starch was metabolized only slowly and remained as a white deposit on the bottom of the tube throughout. This is in contrast to the results reported previously[2] for growth in the presence of chloramphenicol, where all the starch disappeared within 24 hr. and the number of viable bacteria was 10^7/ml. (as determined by the above viable count method); it shows that the number of viable bacteria could be reduced to 1 per cent or less. Nevertheless, since the Protozoa were not broken before the viable counts were carried out, it is possible that, in experiment *A* (Fig. 1) at least, the Protozoa contained many bacteria. It seems probable that in the present experiments the penicillin inhibited the growth of the starch-digesting bacteria, and that the starch remained for the Protozoa to engulf and metabolize. The numbers of viable bacteria reported are not necessarily an accurate estimate of the number actually present, but since there is no one medium which will grow all rumen bacteria, the results may be taken to indicate that the numbers of some of the more easily grown bacteria can be markedly reduced without affecting protozoal growth. Further experiments are in progress in an attempt to reduce the numbers of viable bacteria to still lower levels and to obtain Protozoa that contain no bacteria.

An effect of fresh rumen fluid on the Protozoa was shown in the following experiment. A protozoal culture which was declining in numbers was diluted with an equal volume of fresh complete medium and divided between two tubes. One drop of fresh rumen fluid[1], from which the Protozoa had been removed, was added to one tube; growth of the Protozoa was resumed in that tube but not in the other. In the presence of the fresh rumen fluid the Protozoa divided once or twice in three days without any daily additions, whereas in its absence the numbers declined by 50 per cent in three days.

I wish to thank Miss J. M. How for technical assistance.

Protandry and Self-Fertilization in the Calyptraeidae

ORTON[1] suggested that protandrous animals might be self-fertilizing and that this would be advantageous for the spread of a species. He concluded that *Crepidula fornicata* was self-fertilizing because he found an isolated female guarding veliger larvæ. I have kept single *Crepidula* in aquaria and they have laid fertilized spawn two to three months later. Chipperfield[2] found no unfertilized eggs but he examined only unbroken chains from a densely populated area. Wilczynski[3] has recently said that the typical chains are feeding communities, not breeding associations and that copulation is effected with additional or visiting males. In *Calyptraea chinensis* (L.) males and females begin to associate seven months before spawn is laid[4]. Females probably store foreign sperms for long periods. Evidence for self-fertilization in *Crepidula* is therefore still lacking.

Calyptraea chinensis is a protandrous hermaphrodite and might be self-fertilizing as sperms and ova are found together in the gonad. However, many functional females guard unfertilized eggs. These eggs are more orange than the normal 1–8 cell embryos (stage 1) (ref. 4), lack a definite shape and fertilization membrane and are very fragile. When kept in the laboratory in finger bowls of sea water, these eggs slowly disintegrated into masses of yellow globules whereas normal stage-1 embryos developed so far as the veliger stage. Unfertilized eggs left undisturbed beneath the parent on glass did not develop.

The percentage of unfertilized spawn varied in different years. There was an inverse relationship between association of males with females and the percentage of unfertilized spawn laid the following summer (Table 1). The total number of associated females was undoubtedly higher than that shown, especially in the winter of 1953–54. The period of association was sometimes as short as overnight in laboratory experiments although many associations last for several months in the laboratory and in the Yealm Estuary. I never saw copulation, nor can I find an account of it. The possibility of small numbers of self-fertilizing animals is not excluded. Table 1 shows the percentage of females guarding unfertilized eggs. Females were found which guarded both embryos and unfertilized eggs, even in the same capsule. These were classed as fertile spawn even when only one embryo was found. The total number of unfertilized eggs is therefore greater than Table 1 suggests.

Table 1. ASSOCIATION OF *Calyptraea chinensis* AND SUBSEQUENT PERCENTAGE OF UNFERTILIZED EGGS IN THE YEALM ESTUARY

Percentage of functional females associated in the winter		Percentage of functional females with spawn, guarding unfertilized eggs	
1952–53	unknown	summer 1953	7
1953–54	24	summer 1954	30
1954–55	<5	summer 1955	70

C. chinensis has no free-swimming veliger larva and the hatched animals do not move far. Each male seeks a female and, after association with her, departs to find a smooth surface for his own permanent settlement and change of sex. The surface may be a stone, shell or glass; the only rough surface on which I have found an animal was the ribbed outer shell of *Cardium edule*. The number of suitable surfaces is limited and the stone already occupied by a female must be suitable for a male after association. The number of stones with two or more animals might be greater than that expected by chance. Gregariousness would increase the chance of association and the number of fertile spawnings.

Three samples collected in July, August and September before the main period of association were examined. The numbers of animals on each stone (Table 2) showed no evidence of gregariousness when compared with the expected Poisson distribution.

Table 2. NUMBERS OF *Calyptraea chinensis* FOUND ON STONES IN THE YEALM ESTUARY

No. of associated females	No. of animals not associated	Nos. of stones bearing unassociated animals									
		1	2	3	4	5	6	7	8	9	Total
21	1,168	762	110	40	7	2	2	1	0	1	925

Calyptraea chinensis in the Yealm Estuary was neither self-fertilizing nor gregarious. It is doubtful whether the protandrous Calyptraeidae are self-fertilizing, and if some animals are, the number of embryos so produced is probably small.

Suppression of Cytoplasmic Division in *Amoeba proteus*

CYTOPLASMIC division in *Amoeba proteus* can be suppressed by the application of strong light during the division process[1]. The same can be achieved as follows. Division is allowed to proceed undisturbed until nuclear division is complete. When the cell becomes elongated and the division furrow appears, slight pressure with a glass needle is applied for short intervals alternately on each one of them, thus shifting parts of the liquid endoplasm back and forth from one prospective daughter cell into the other. After about 7–10 min. of such treatment, without having completed the cleavage the cell resumed its normal interphase appearance. The surface, which had been covered with blebs, becomes smooth, pseudopodia are formed, and the cleavage furrow gradually disappears. Pressure applied for the same length of time before the completion of nuclear division does not prevent either nuclear or cytoplasmic division. Once the furrowing process is suppressed no cytoplasmic division occurs before the next full cell division about 20–28 hr. later.

The observation that the prevention of cytoplasmic division by pressure applied for a minimum time of 7–10 min. is sufficient to postpone it for one full cellular cycle suggests that the completion of chromosome duplication has itself a reversing influence upon the factors involved in cytoplasmic division. The minimum time which this influence requires to become effective is provided in the experiment by the artificial retardation of the furrowing process. If the initiation of both nuclear and cytoplasmic division were controlled by the ratio between utilization and production of chemically bound energy[2-4], the increased rate of energy-utilizing macromolecular synthesis after mitosis[5-7] could be the mechanism for this reversal.

Albinism in an American Population of the Shore Crab, *Carcinus maenas* (L.)

THE common shore or green crab, *Carcinus maenas* (L.), is a widely distributed predator in inshore areas on both sides of the Atlantic. The ecological importance of the green crab, its status as a predator on commercial shellfish, and its extensive use in laboratory studies warrant a preliminary report on a recently noted abnormality found in a population of this species near Woods Hole, Massachusetts.

Two female *Carcinus maenas* with abnormal coloration were discovered by me in the summer of 1958 at Menemsha Creek, Martha's Vineyard Island, Massachusetts. In one specimen the right cheliped was entirely lacking pigment, appearing chalky white. The second specimen was similarly affected in all segments of a walking leg. The crabs, which had mated prior to capture, were isolated in running sea water at the Massachusetts State Lobster Hatchery and Research Station, and in November of 1958 they both became ovigerous. The white-clawed individual lost all her eggs during confinement; but the last of these were well developed by the time they became unattached. The second crab retained a part of the egg mass to the hatching stage. During March 20–30, 1959, slightly more than 700 eggs hatched from this female, 15 of them yielding larvæ totally lacking pigment except for the eyes. This group, slightly less than 2 per cent, were completely transparent and very readily separable from their siblings. Had they survived they probably would have become totally white adults. Relatively small amounts of white such as present on the parent crab would have been indistinguishable in the larval stages, and thus it is possible that some of the 'normal' larvæ also would have exhibited some albinism had they attained the adult form.

An attempt was made to rear all the larvæ but *Artemia* nauplii provided as food were apparently too large for the larvæ to utilize and other foods were not available at the time. Within 23 days of initial hatching all larvæ had died from starvation or other adverse cultural conditions, but there was no apparent tendency for albino larvæ to succumb more quickly than the others.

Discovery of several additional albino adults in the tidal creeks near the Lobster Hatchery some 10 miles from Menemsha indicated that the anomaly was not restricted to a single locality. Indeed, John Ropes of the Narragansett Marine Laboratory has since found partially albino green crabs in Rhode Island waters and even in Plum Island Sound, Massachusetts, north of Cape Cod.

To determine the frequency of occurrence of this abnormality in a natural population a trapping survey was undertaken during the summer months of 1959, near the Lobster Hatchery. The traps used were of 1-in. chicken wire mesh, and very young crabs were not retained. The results, therefore, are based only on adults and large juveniles. Prior to May 26, 1959, a total of 5 albino crabs had been captured in Martha's Vineyard waters. Between May 26 and July 31, 1959, a total of 1,595 green crabs was trapped of which 45, or 2·9 per cent, were partial albinos. The degree of albinism exhibited varied considerably. Thirty-one specimens had only one dactyl affected, whereas some specimens had several entire appendages white. In two specimens a white maxilliped was found, and several individuals had white sternal plates. At least two specimens were irregularly mottled on the carapace and other portions of the body. Specimens which moulted in captivity showed the same degree of albinism after moulting as before. There was no indication that the abnormal coloration was the result of injury or regeneration.

The incidence of 3 per cent reported here for an adult population may be lower than the frequency for the population as a whole, for trapped animals often had one or more appendages missing which would tend to reduce apparent incidence. If selective predation tends to eliminate those individuals showing large white areas, the adult incidence is probably less than in a juvenile population.

The wide variation in degree of albinism suggests more than one gene may be responsible for inheritance and/or exhibition of the character, but controlled laboratory matings will be necessary to study the inheritance of this condition in more detail.

At the time the data were collected I was employed by the U.S. Fish and Wildlife Service, Bureau of Commercial Fisheries, Milford, Connecticut. I wish to thank Dr. V. L. Loosanoff, director of the Milford Laboratory, for permission to undertake this study.

Chordotonal Organs in Crustacea

THERE is a series of proprioceptor organs in the joints of the walking legs of decapod Crustacea, each consisting of a strand of elastic connective tissue with which are associated bipolar sensory nerve cells. These organs have been mentioned by Alexandrowicz and Whitear[1] and by Alexandrowicz[2]; work on their physiology has been published by Burke[3], Wiersma and Boettiger[4] and by Wiersma[5]. An electron microscope study of these organs in *Carcinus maenas* has now shown that they are chordotonal organs; the distal processes of the sensory cells are associated with scolopales.

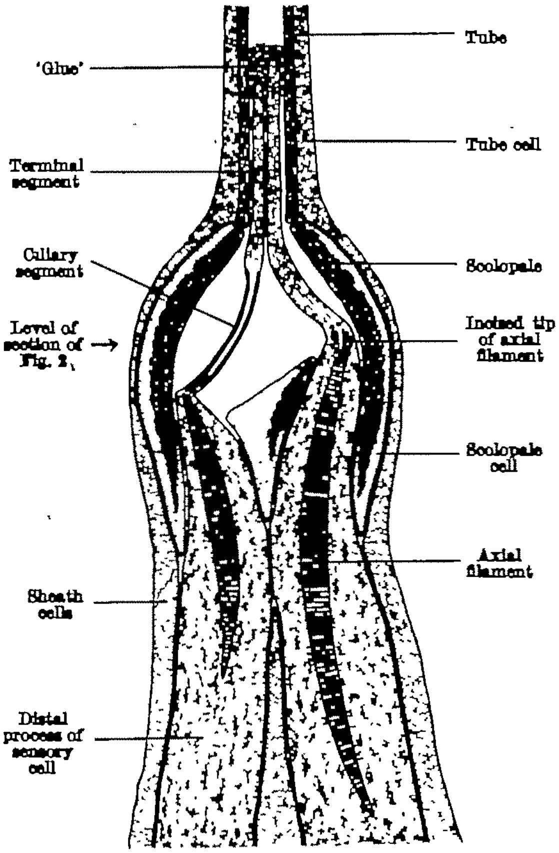

Fig. 1. Diagrammatic longitudinal section of a heterodynal scolopidium of the propodite-dactylopodite chordotonal organ, not to scale

In the organ spanning the propodite-dactylopodite joint each scolopidium receives the distal processes of two sensory cells; these are dissimilar in their fine structure. Following Debauche[6], who described scolopidia with paired sensory cells in certain insect chordotonal organs, such a scolopidium may be described as *heterodynal*. The structure is illustrated diagrammatically in Fig. 1. All the parts shown are embedded in the connective tissue of the strand; the nerve cell bodies may lie within the strand, or alongside it. Proximally, the distal processes of the sensory cells are wrapped in sheath cells which separate them from the connective tissue of the strand. Where a pair of distal processes become associated they are separated by a sheath cell, but after a certain distance this withdraws from between them, so that the cell membranes of the two sensory cells are in apposition, separated only by a 200–300 Å. gap. The two processes then enter the base of the scolopale, and become separated again by an intrusive projection of the scolopale cell. The scolopale itself is an intracellular organ consisting of an agglomeration of fibrous material which is markedly electron-dense. The scolopale cell encloses a space, 2–5μ across, which is presumably filled with fluid during life. Within the scolopale, the distal processes of the sensory cells narrow, and at first lie against the wall. They then change their structure and pass across the scolopale cavity to enter a tube, the lumen of which is continuous with the scolopale space. This tube, which corresponds to the 'terminal bundle' or 'terminal fibre' of classical descriptions of scolopidia, is an extracellular organ, presumably formed by a pair of cells which lie on either side of it. The walls of the tube consist of an amorphous substance which is vacuolated at intervals. The tube continues distally some way beyond the ends of the distal processes of the sensory cells, but eventually ends within the connective tissue strand; it does not reach so far as the exoskeleton.

As the distal processes of the sensory cells approach and enter the scolopale, each contains an *axial filament*, which is a rod about 0·5μ in diameter, tapering at the ends. It has transverse striations with a total interval of about 800 Å. Distally the axial filament ends where the sensory cell process leaves the wall of the scolopale; mitochondria occur in the cytoplasm of the cell process up to this point, but not beyond it. One of the two dissimilar sensory cell processes (that on the left in the diagram) as it passes into the lumen of the scolopale acquires a fine structure somewhat like that of a cilium, with nine peripheral microfilaments; there are, however, no central microfilaments. This part of the sensory cell process, the *ciliary segment*, is about 0·3μ in diameter. Before leaving the scolopale, the distal process thickens and loses the ciliary structure; instead of nine peripheral filaments it contains numerous microtubules, each about 200 Å. across. This part of a sensory cell process may be called the *terminal segment*. In the second sensory cell process (on the right in the diagram) the axial filament is longer than in the first cell, and extends somewhat farther up the scolopale wall, often partially wrapped by a ridge of the scolopale. At its distal end this axial filament becomes incised and vacuolated, so that in transverse section its extreme tip appears as an annulus with radiating buttresses. The ciliary segment as such is lacking, although in some cases there are indications of a ninefold structure immediately beyond the tip of the axial filament. As it crosses the lumen of the scolopale, the cell process has the structure of a terminal segment, with microtubules.

Fig. 2 is an electronmicrograph of a transverse section of a heterodynal scolopale showing the ciliary segment of one cell process and the incised tip of the axial filament of the other.

Both terminal segments run for a certain distance into the tube. Near their ends they become surrounded by an ill-defined substance which in Fig. 1 is referred to as 'glue', in consequence of its supposed function of fastening the terminal segments into the tube. One of the distal processes generally extends slightly farther than the other, but they both end within the 'glue'; more distally the tube appears empty.

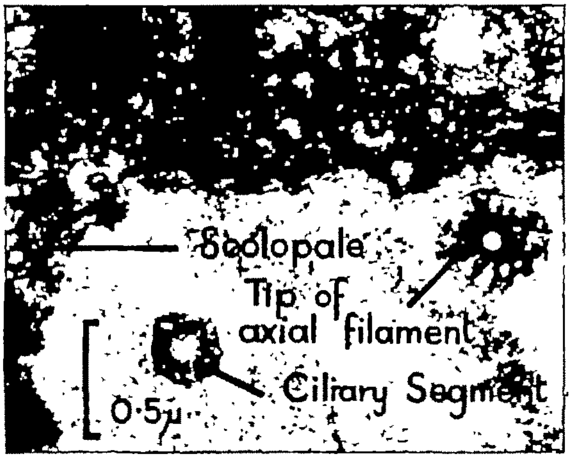

Fig. 2. Electronmicrograph of a transverse section of part of a scolopale of the propodite-dactylopodite organ; the level of the section is indicated in Fig. 1. Specimen fixed in osmium tetroxide, stained with phosphotungstic acid, and embedded in 'Araldite' epoxy-resin

All the scolopidia seen in the propodite-dactylopodite chordotonal organ have been heterodynal. According to Wiersma and Boettiger[4], the distal cells are 'position' and the proximal cells 'movement' receptors; no morphological differences between the scolopidia in the two positions have been detected, except in the size of the cell bodies.

There are two chordotonal organs associated with the carpopodite-propodite joint; *CP* 1 does not cross the joint, *CP* 2 does. All the scolopidia seen in *CP* 1 have been heterodynal, wherever situated. In *CP* 2, on the other hand, all the scolopidia seen have had associated with them only one sensory cell; it is proposed to refer to scolopidia of this type as *monodynal*. In all the cases seen, the distal process has been of the type with a ciliary segment. Apart from the lack of a second cell process, the structure of a monodynal scolopidium is as described above.

The organs in the meropodite have not yet been investigated with the electron microscope. The organ of the coxo-basipodite joint, *CB*, has scolopidia with paired distal processes, which are similar to one another, both being of the type with a ciliary segment. Following Debauche[6], such scolopidia are *isodynal*. Their structure otherwise resembles that of the heterodynal scolopidia.

Many of the structures described in these crustacean scolopidia, for example, the scolopale, axial filament and ciliary segment, may be compared directly with those in the scolopidia of the auditory organs of *Locusta migratoria*, recently described by Gray[7].

Any discussion of the functions of the types of scolopidia described above is speculative. So far as the propodite-dactylopodite and carpopodite-propodite organs are concerned, it would not be inconsistent with the results of Wiersma and Boettiger[4] and of Wiersma[5] to suppose that, in the heterodynal scolopidia, one sensory cell responds to stretching of the terminal segment, and the other to its slackening. The apposition of the two distal processes, proximal to the scolopale, suggests that they are capable of interacting in some way, perhaps of modifying one another's response. The presence of monodynal scolopidia in *CP* 2 would be consistent with Wiersma's report that the response of this organ is commonly to movement in one direction only. There are no published results on the responses of the coxo-basipodite organ, so that nothing can be said about the functions of isodynal scolopidia; it should be noted, however, that this is the only chordotonal organ of the series investigated which is not attached to a muscle tendon.

Various anomalies have been seen, particularly in the structure of non-ciliary processes of the heterodynal scolopidia, for which no explanation can be given as yet. The receptor organs at the bases of the legs of decapods, described by Alexandrowicz and Whitear[1] and by Alexandrowicz[2], are also being investigated by electron microscopy. It need only be mentioned at present that the muscular receptor organ and the innervated elastic strands are not chordotonal organs, and show none of the elaborations of structure described here.

Effects of Light and Darkness on the Rhythm of Output of Carbon Dioxide of Excised *Bryophyllum* Leaves

IT has been shown by Wilkins[1,2] that if excised leaves of the succulent plant *B. fedtschenkoi* are maintained in darkness, at a constant temperature of 26° C. and in an air-stream initially free of carbon dioxide they exhibit a 22·4-hr. rhythm in their rate of output of carbon dioxide. Furthermore, it was found that continuous illumination inhibited the rhythm, which recommenced when darkness was restored. A more detailed investigation of the light inhibition of the rhythm has been made by illuminating leaves for a few hours at various positions in the cycle.

If leaves are illuminated for 3 (Fig. 1*A*) or 6 hr. at an intensity of 3,000 lux between the peaks the phase is reset so that the first post-treatment peak occurs approximately 19 hr. after the end of the treatment. The degree of phase shift is therefore determined not by the duration of the treatment but by the time at which it terminates. Illumination for 1 hr., even at an intensity as high as 20,000 lux, has little or no effect upon the phase. On the other hand, up to 5 hr. illumination at an intensity of 3,000 lux applied at the crest of a peak did not reset the phase (Fig. 1*B*). Thus, the phase of a rhythm persisting in leaves in darkness varies in its sensitivity to a 3-hr. light treatment; it is reset by a treatment applied between, but not at the crests of, the peaks.

Over the range 8–3,000 lux, the intensity of illumination during a 6-hr. light treatment applied between the peaks has no effect on the efficiency with which that treatment resets the phase; the phase delay is determined by the time at which darkness is restored. At an intensity of 2 lux, however, the phase delay is equal to the duration of the treatment.

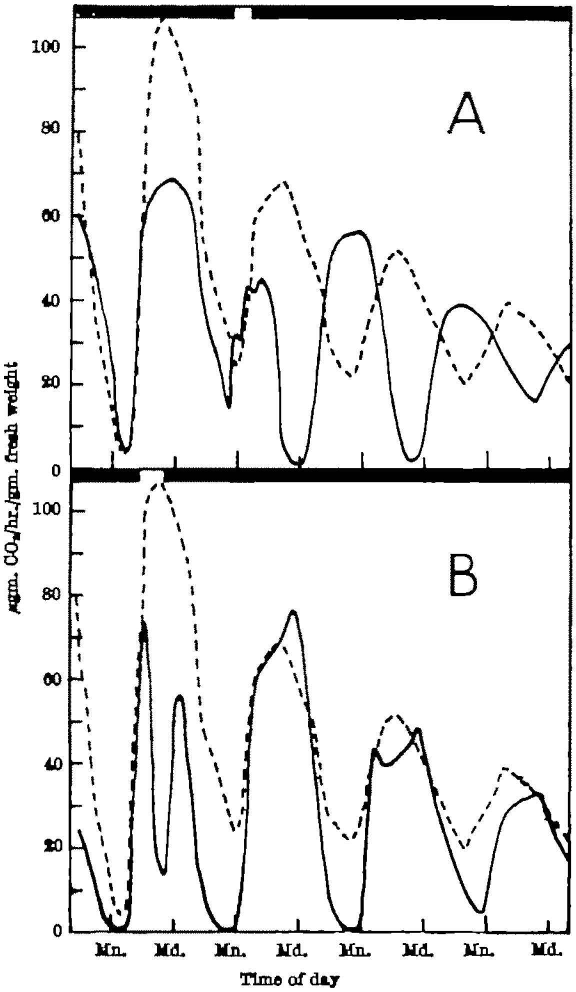

Fig. 1, *A*. Showing that 3-hr. illumination at an intensity of 3,000 lux, applied between the peaks, resets the phase of a rhythm persisting in darkness and at 26° C. *B*, showing that 6-hr. illumination at 3,000 lux applied at the crest of the peak does not reset the phase Illumination programme shown by the bar above each figure. Ordinates: μgm. carbon dioxide/hr./gm. fresh weight. Abscissae: Time of day, Mn. = midnight, Md. = noon. Control experiment in continuous darkness throughout shown by the broken lines

Wave-lengths of light greater than 565 mμ are responsible for inducing a phase shift. A 6-hr. red light treatment at an intensity of 850 ergs/cm.^{2}/sec. applied between the peaks resets the phase in a manner similar to a 3,000-lux white light treatment, whereas 6-hr. illumination with blue light (below 525 mμ) at an intensity of 10,860 ergs/cm.^{2}/sec. has no effect upon the phase. Moreover, continuous red light completely inhibits the rhythm, which recommences in blue light.

Clearly, whether or not a light treatment resets the phase of the rhythm depends on its wave-length, duration and intensity, and the time in the cycle at which it is administered.

It was previously observed that continuous illumination strongly inhibits the rhythm; but experiments carried out to determine the effect of changing the intensity of light to which leaves were exposed revealed that a rhythm is initiated in illuminated leaves if the intensity is reduced, either suddenly or gradually, by at least 80 per cent. The effect of a given intensity on the rhythm depends, therefore, on the intensity by which it is immediately preceded. For example, exposing leaves to an intensity of 500 lux inhibits a rhythm which was previously persisting in darkness (Fig. 2*A*), but initiates a rhythm in leaves which had previously been exposed to the higher intensity of 2,500 lux (Fig. 2*B*). A rhythm induced in this way in illuminated leaves will persist so long as a rhythm in darkened leaves and its phase is determined by the time at which the intensity is reduced. Over the range 0–500 lux, the period is unaffected by the intensity of white light to which the leaves are exposed.

Further experiments were carried out to determine whether or not the phase of a rhythm persisting in illuminated leaves was reset by interrupting the illumination with a few hours darkness and, if this was so, whether it was equally responsive to a short dark treatment applied at different positions in the cycle. A rhythm was initiated by illuminating leaves at an intensity of 3,000 lux for 13 hr. and then reduc-

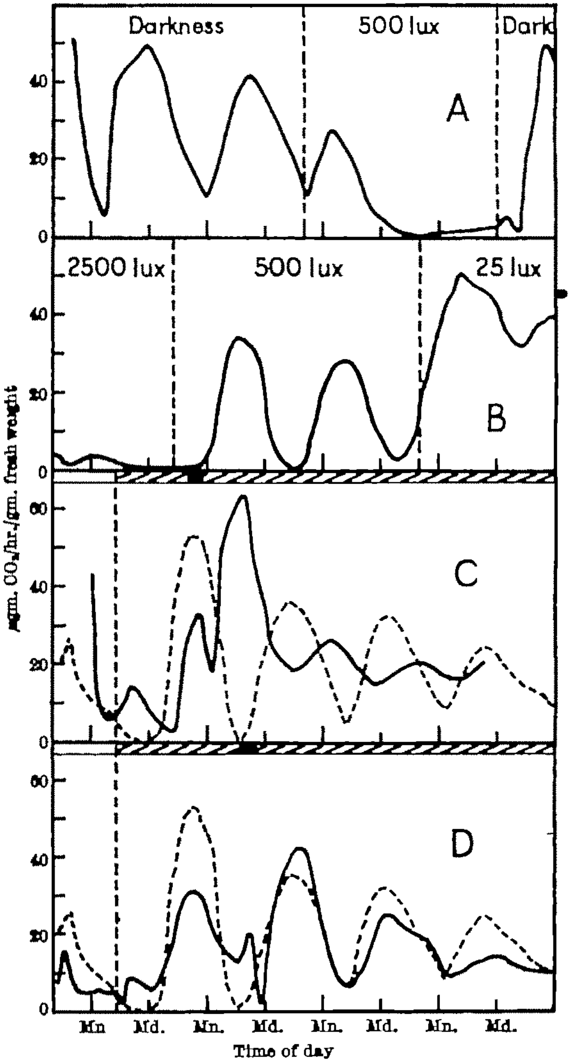

Fig. 2, *A* and *B*. Showing effect on the rhythm of changing the intensity of illumination to which the leaves are exposed. An intensity of 500 lux inhibits a rhythm in leaves previously exposed to darkness (*A*), but initiates a rhythm in leaves which were previously exposed to an intensity of 2,500 lux (*B*). *C* and *D*, showing that the phase of a rhythm in leaves illuminated at an intensity of 100 lux (hatched area in the illumination programme bar) is reset by 3 hr. darkness applied at the crest of a peak (*C*) but not between the peaks (*D*). Control experiment in 100 lux throughout shown by the broken lines. Unshaded area of illumination bar indicates that leaves were exposed to an intensity of 3,000 lux ing the intensity to 100 lux (broken curves in Figs. 2C and 2D). The phase is reset by darkening leaves for 3 (Fig. 2C), 6 or 9 hr. at the crest of a peak. The amount of phase shift is determined by the duration of the treatment, increasing to a maximum with 9-hr. darkness. On the other hand, the phase is unaffected by darkening leaves for 3 (Fig. 2D) or 6 hr. between the peaks. The phase of a rhythm persisting in illuminated leaves varies in its sensitivity to a 3-hr. dark treatment, being reset by a treatment applied at the crests of, but not between, the peaks. This variation is in the opposite sense to that of the phase of a rhythm in darkened leaves to a 3-hr. light treatment.

The phase of a rhythm in illuminated leaves is, however, reset when the light is permanently extinguished at a point between, or at the crests of, the peaks. Thus, while 6-hr. darkness applied between the peaks does not affect the phase, continuous darkness commencing at a similar time induces a phase shift.

The effects of light and darkness on the rhythm differ in two respects. If leaves having a rhythm persisting in light are exposed to continuous darkness only the phase is shifted, the rhythm is not inhibited as it is when leaves which have been kept in darkness are exposed to continuous light. Further, the minimum duration of light treatment required to induce maximum phase shift in a rhythm persisting in darkness is less than 3 hr., whereas more than 6-hr. darkness is required to induce maximum phase shift in leaves having a rhythm persisting in light.

In general, the reactions of the endogenous rhythm in *Bryophyllum* to changes in conditions of illumination closely resemble those of the rhythm of luminescence in *Gonyaulax polyedra*[3]. A more complete description of this work and a detailed comparison of the results with those of other authors will be published elsewhere.

ENTOMOLOGY

Recognition of Nulliparous Mosquitoes without Dissection

DURING the age-grading of female mosquitoes it frequently happens that a large proportion of the dissecting time is devoted to the recognition of those that are nulliparous, when it is usually only the parous ones which require detailed examination. Such a difficulty is encountered to a marked degree in large samples of forest mosquitoes in Uganda, of which more than 95 per cent may be nulliparous. It is therefore desirable to establish means whereby as many nullipars as possible can be recognized without dissection. The use of two external characters for age-grading mosquitoes has been suggested previously[1,2], but only recently have techniques become available[3] whereby their reliability can be adequately checked. The work reported here was undertaken to determine whether these and two other external characters could be used with confidence to distinguish nullipars of certain African mosquitoes. The condition of each mosquito was checked by dissection of the ovaries[4]. Results show that in certain species the use of these characters can enable up to 90 per cent of nullipars to be recognized, thereby effecting a great economy in the age-grading of samples.

External wear. Variation in external wear was suggested as a means of age-grouping by Perry[1]. This character can be valuable if its use is restricted to recognizing only those females so fresh as to be certainly nulliparous. Once the minimum amount of wear associated with the first oviposition has been assessed, thereafter all individuals showing less wear can be classified as nulliparous. To establish the appropriate level of minimum wear in *Mansonia* (*Coquillettidia*) *metallica* Theo. and *M.* (*C.*) *fraseri* Theo. about 500 females of each species were first examined and dissected, and then reliability trials were conducted. Subsequent errors were extremely small. Of those classified as 'nulliparous', 8/938 (0·9 per cent) of *M.* (*C.*) *metallica* and 1/946 (0·1 per cent) of *M.* (*C.*) *fraseri* were parous; whereas among those classified as 'doubtful' 97/225 (43·1 per cent) and 60/143 (42·0 per cent) were parous, respectively. It has been found, moreover, that by adopting a slightly more severe criterion of minimum wear and achieving a greater familiarity with the species concerned, these errors can be reduced still further. In these samples the number of nulliparous mosquitoes dissected unnecessarily was reduced from 93 to 10 per cent. The amount and type of wear that is critical must be assessed independently for each species. Denuding of the abdominal sternites is the best guide in *Mansonia* (*Coquillettidia*), whereas wing fray is more reliable in *Mansonia* (*Mansonioides*) *africana* Theo., *M.* (*M.*) *uniformis* Theo. and *Aëdes*.

Parasitic mites. Gillett[5] suggested that hydrachnid mites could be used to age-grade swamp-breeding mosquitoes. Subsequent attempts to determine their reliability by dissection[5,6] have shown that, although the great majority of infested females are nulliparous, mites occasionally occur on parous ones also. In the present work it has been found that, although in some species more than 30 per cent of parous mosquitoes may carry mites, in nearly every case the latter are either dead or else not hydrachnids. Female mosquitoes which bear living hydrachnids are almost always nulliparous (Table 1). It is considered likely that the few exceptions recorded in Table 1 were due to initial failure to recognize those mites which were dead. In *M.* (*C.*) *fuscopennata* Theo., for example, hydrachnid mites die on at least 5 per cent of infested females before their first oviposition, and thereafter

Table 1. INFESTATION OF MOSQUITOES WITH LIVING HYDRACHNID MITES

Species	Nulliparous		Parous	
	Total examined	Percentage bearing hydrachnids	Total examined	Percentage bearing hydrachnids
M. africana	266	65·8	179	2·8
M. fuscopennata	1,594	52·1	676	2·5
M. uniformis	39	43·6	36	2·8
C. annulioris	366	14·2	330	0·3
M. metallica	3,904	10·4	384	—
M. aurites gp.	198	8·6	35	—
M. fraseri	4,944	8·3	410	—
M. maculipennis	197	4·6	20	—
M. pseudoconopas	1,666	2·2	54	—

remain attached to the host. The percentage of mites dying on the host varies according to the species of mite and mosquito, but has so far proved to be highest in *M.* (*C.*) *fuscopennata*. Such characters as shape, pattern, colour, site of attachment and associated scars indicate the kind of mite, whereas its shape and colour can show whether it is alive or dead. If these reservations are observed, hydrachnid mites can provide a valuable means of recognizing nulliparous mosquitoes.

Colour of integument. In *M.* (*C.*) *pseudoconopas* Theo. the colour of the thoracic pleura changes during adult life from apple-green to brownish yellow. If three progressive colour grades are recognized, it is found that all females in the first are nulliparous. The proportion of parous individuals encountered in each colour grade during trials were: green 0/606 (0 per cent); pale green 10/564 (1·8 per cent); and yellow 34/123 (27·6 per cent). Only about 20 per cent of parous females remain in the second colour grade after having laid eggs once. It has been found that most nullipars in the second grade can be recognized on abdominal wear, and that this often leaves only about 10 per cent of a sample to be dissected. In this species the existence of a colour sequence enables non-hydrachnid mites to be used as an additional guide to age, since these are small at the beginning of each gonotrophic cycle but large at the end of it. Thus their size can often make certain an otherwise doubtful diagnosis. About 36 per cent of *M.* (*C.*) *pseudoconopas*, nulliparous and parous, bear this kind of mite. Colour changes similar to, though less obvious than, those found in *M.* (*C.*) *pseudoconopas* occur in other mosquitoes. In some (for example, *Anopheles* (*Anopheles*) *implexus* Theo., *M.* (*C.*) *maculipennis* Theo. and *Culex* (*Lutzia*) *tigripes* Grp. and C.) the change takes longer and is not completed before the first oviposition, but in others (for example, *M.* (*C.*) *metallica*, *M.* (*C.*) *fuscopennata*, *M.* (*C.*) *aurites* Theo. gp., *M.* (*C.*) *fraseri* and *C.* (*Culex*) *annulioris* Theo.) females with greenish areas on thorax or abdomen are invariably nulliparous. In *M.* (*C.*) *metallica* up to 26 per cent of nullipars can be recognized in this way.

Presence of meconium. In younger nullipars of certain species with a pale abdominal integument (for example, *Coquillettidia* spp.) the meconium is clearly visible in abdominal segments 4 and 5. In catches of resting mosquitoes, up to 34 per cent of nulliparous *M.* (*C.*) *fraseri* may still retain it.

Other characters. If nulliparous females have to be dissected, they can often be classified quickly on two other characters. The first is the degree of resilience of the abdomen, which can differ markedly in nulliparous and parous individuals. The second is the presence of 15–30 discrete disks of fat in the abdominal cavity, as found in *Toxorhynchites*, *Coquillettidia* and *Eretmapodites*. These disks disintegrate during the first gonotrophic cycle, and in *Coquillettidia* usually before the first blood meal.

It is intended to publish a full account of this work elsewhere.

Ovarioles as a Meristic Character in Coleoptera

INSECT ovaries are bilateral structures (except in certain aphids) which contain 1–3,000 egg tubes or ovarioles. In Coleoptera, the ovarioles are polytrophic and acrotrophic in the sub-orders Adephaga and Polyphaga, respectively (see, however, Bonhag[1]). As the meristic nature of the beetle ovary has not been particularly studied, and because of the possible importance of the ovariole number as an aid to systematics, a study was undertaken.

The ovaries were removed by vivisection, placed on depression slides containing 0·8 per cent saline, and examined with a dissecting microscope. A list of the ovariole numbers in some families, arranged in the order of Leng[2], is given in Table 1.

Table 1. OVARIOLE NUMBERS (ONE OVARY) IN COLEOPTERA*

	Mean	Range	Species	Genera
Cicindelidae	10	9–12	3	1
Carabidae	10	4–21	33	14
Dytiscidae	15	14–40	6	6
Hydrophilidae	15	13–20	7	6
Silphidae	20	12–40	5	2
Staphylinidae	7	3–10	16	12
Lampyridae	20	8–27	4	4
Meloidae	86	12–200	5	4
Elateridae	19	4–33	9	6
Cucujidae	3	2–8	12	5
Coccinellidae	17	2–51	55	26
Tenebrionidae	20	4–52	6	5
Scarabaeidae	6	5–7	14	12
Cerambycidae	30	27–33	3	3
Chrysomelidae	13	5–25	20	16
Curculionidae	2	1–2	36	25
Scolytidae	2	2–2	14	10

* A partial listing of work on 45 families or 287 species, 106 of which have been determined by me.

A wide range of 1–200 ovarioles occurs within the Coleoptera. There is, however, relatively little intrafamilial variation in ovarioles (usual number in parentheses) in the Staphylinidae (5), Cucujidae (3), Scarabeidae (6), Curculionidae and Scolytidae (2). While similar values occur in other families they are part of an extensive interspecific range in ovariole number. Thus the Silphidae, Lampyridae, Elateridae, and Tenebrionidae, which average close to 20 ovarioles, contain large interspecific differences (2–52). The highest values are found in the Meloidae and Cerambycidae, which have 86 and 30 respectively. The Cerambycidae show a narrow range (27–33), but in the Meloidae it is very great (12–200). Prominent differences can often be observed between subfamilies and between tribes. The Coccinellidae and Coccinellinae and Epilachninae average 16 and 27, respectively; within Coccinellinae, the Hyperaspini, Scymnini, Psylloborini and Coccinellini have values of 7, 6, 13 and 21, in that order.

While many species contain a constant number of ovarioles just as many show an intraspecific variation. For example, *Harpalus pennsylvanicus* DeG. and *Chauliognathus pennsylvanicus* DeG. have means of 10 ± 1·8 and 47 ± 11·9, respectively. Where species were sampled from two localities different values were obtained. Thus *C. pennsylvanicus* from Penn Park, Pa., have 34 ± 15·5 ovarioles, whereas 47 ± 11·9 obtain at Ottawa, Ontario. Within individuals a difference in ovariole number between left and right ovaries was often noted; *Plagiodera versicolor* Laich. and *Coccinella novemnotata novemnotata* Hbst. are examples. In *Drosophila melanogaster* Meig. it is thought that this asymmetry results from disturbance of embryonic processes that precede ovariole development[3].

A detailed report on the numbers of ovarioles and their structure is being prepared for publication. I am indebted to Mr. W. J. Brown of this Institute for identification of species and assistance with problems of synonymy.

Nutritive Values of Carbohydrates for the Silkworm, *Bombyx mori*

NUTRITIONAL requirements for carbohydrates in insects have been widely studied[1], but not enough in the leaf-eating forms. This is mainly due to the fact that there are difficulties which must be solved before the determination of their nutritional requirements, namely, in devising a suitable test diet. In the silkworm, *Bombyx mori*, the nutritive value of the mulberry leaves has hitherto been discussed on the basis of the analytical data of leaf components as well as of the rearing experiments of larvæ. Though many efforts have been made to formulate a chemically defined diet for this insect, no suitable one has so far been made available. I have recently tried to determine the nutritive values of carbohydrates for the silkworm by means of oral administration of them.

Newly moulted, unfed fifth instar larvæ were used. All substances were supplied in the form of either a solution or a suspension and no leaf was offered to the larvæ[2]. A hypodermic needle mounted on a syringe was inserted from the mouth opening into the gut lumen and a known volume of such a solution (10 per cent, w/v) was administered once a day. The larvæ were kept at room temperature and weighed every day until death. Ten larvæ were used for one substance in each experiment. Data on survival tests have been calculated as the number of days that the larvæ remained alive, in other words, days to 100 per cent mortality. The mean was obtained by dividing the summation of days for each larva in one group by ten, as summarized in Table 1.

Table 1. SURVIVAL OF SILKWORM LARVÆ ADMINISTERED WITH VARIOUS CARBOHYDRATES

Carbohydrate	Mean length of survival (days)		
	Experiment 1	Experiment 2	Experiment 3
Pentoses			
L-Arabinose	3·3	3·3	4·1
L-Rhamnose	3·2	2·9	4·0
D-Ribose	4·0	4·4	5·5
D-Xylose	5·9	7·8	9·8
Hexoses			
D-Fructose	6·1	5·6	7·7
D-Galactose	5·1	5·5	5·7
L-Sorbose	2·3	3·0	3·4
D-Glucose	6·8	7·1	7·9
D-Mannose	6·9	7·8	7·7
Disaccharides			
Sucrose	6·8	7·1	8·2
Maltose	5·9	6·9	6·2
Lactose	5·8	7·9	8·5
Cellobiose	7·2	8·7	8·3
Trehalose	6·9	6·3	8·2
Melibiose	6·2	7·3	8·4
Trisaccharides			
Raffinose	7·5	7·8	7·7
Melezitose	8·6	8·2	8·6
Glycosides			
α-Methylglucoside	3·5	3·2	4·3
α-Methylmannoside	2·7	2·8	3·6
Sugar alcohols			
Inositol	—	5·3	6·2
Mannitol	—	—	8·3
Dulcitol	—	2·6	3·8
Sorbitol	6·2	8·3	9·7
Polysaccharides			
Dextrin	—	6·0	9·6
Starch	—	—	5·4
Water	3·1	2·8	3·5
Starved	3·1	3·4	4·4

Any carbohydrate which increases survival beyond that of the control larvæ supplied with water alone can be assumed to be of nutritive value. Control larvæ usually survived for three days or a little longer and died somewhat sooner than those starved.

Among four pentoses tested, only xylose is utilized and arabinose and rhamnose are of little or no value. Ribose is slightly better than those two. Of the hexoses, glucose, fructose and mannose are good; galactose is of moderate value, while sorbose is exceptionally bad. The disaccharides are uniformly good. The trisaccharides raffinose and melezitose are well utilized. Both glycosides tested are scarcely utilized. Among alcohols, sorbitol and mannitol are utilized, but inositol is intermediate, and dulcitol is of no value. Dextrin is also good and much better than starch.

The results on the increase in body-weight also supported that on survival tests; carbohydrates increasing the length of life resulted in an increase in body-weight, while those not increasing survival were generally of no effect on the weight or rather often inhibitory. Thus, it is of interest that the nutritional requirements for carbohydrates by the silkworm are in good agreement with those of many other insects in many ways, even though there are great differences between insect species in the survival value of certain compounds.

Preferences for sugars have also been studied with this insect[3], and it is concluded that there is no correspondence between the nutritive value of various sugars and preference for them. Sugars which are preferred most and are of high nutritive value are sucrose, fructose and raffinose.

GENETICS

Autogenous Necrosis in an *Antirrhinum* Species Hybrid

HERITABLE plant tumours have been found in interspecific hybrids of *Nicotiana*[1,2], particularly in the hybrids of *N. glauca* × *N. langsdorffii*. Seldom, however, have they been found in any other plant material; an inbred line of clover[3] and interspecific hybrids of *Datura*[4] being possible extensions of the

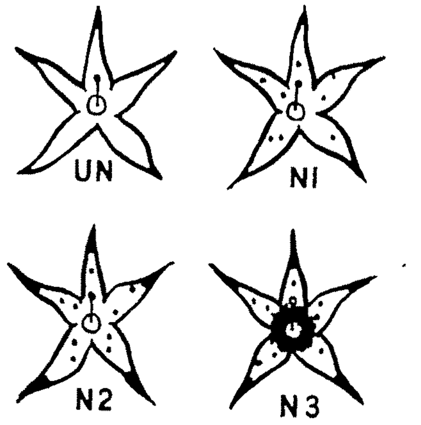

Fig. 1. Degrees of necrotic spotting on the calyces of *A. orontium* × *A. meonanthum* hybrids

phenomenon. Autogenous necrosis, also an infrequent pathological condition but perhaps genetically analogous to some cases of tumour formation, has been observed and analysed in hybrids of *Lycopersicon* species and wheat varieties[5,6]. The results presented here have many similarities with the variable production of necrosis in some wheat hybrids, but the sterility of the *Antirrhinum* material prevented further analysis.

The necrosis in *Antirrhinum orontium* × *A. meonanthum* appears as excrudescent, corky spots on the stems, leaves and calyces, together with occasional lesions on the stems. The degree and position of these effects varied according to the origin of the parent plants (see Table 1 and Fig. 1). The hybrid was also found to be sterile, no chromosome-pairing occurring at meiosis, and it could only be produced when the self-fertile *orontium* species was the female parent and the self-incompatible *meonanthum* the male[7]. Many interspecific hybrids have been made within the genus, but only the *orontium* × *meonanthum* hybrid has shown this abnormal pathological condition.

Table 1

A. orontium ♀	*A. meonanthum* ♂			
	Penacova origin		Coimbra origin	
	Cross-compatible plants *A*	*B*	Cross-compatible plants *A*	*B*
Kew origin	*L* *N2*	*LL* *N3*	*UL* *UN*	*UL* *UN*
Sacavem origin	*L* *N1*	*LL* *N1*	*UL* *UN*	*UL* *UN*
Var. *parviflorum*	—	*LL* *N3*	*UL* *UN*	*UL* *UN*

UL, Unaffected by lesions on stem; *L*, lesions on stem; *LL*, severe lesions; *UN*, unaffected by necrotic spots; *N1*, necrotic spots on stems, leaves and calyces; *N2*, necrotic spots on stems, leaves and calyces and on all tips of calyces; *N3*, like *N2*, but centre of calyces badly affected by necrosis.

Although no phenotypic differences can be seen between *orontium* plants obtained from Kew and those from Sacavem (Portugal), the F_1's of these with *meonanthum* show different expressions of necrosis. Likewise, in *meonanthum*, no phenotypic differences could be seen between the Portuguese (Penacova and Coimbra) lines but, even when cross-compatible plants within the Penacova line were tested, the associated, although not necessarily correlated, differences in genetic constitution were sufficient to influence the expression of stem-lesions and necrosis in the hybrid. Hybrids involving the Coimbra *meonanthum* never showed any lesions or necrosis; these hybrids, moreover, although still sterile, were much more vigorous and germinated better than the hybrids incorporating the Penacova line.

Crosses of *orontium* (Kew) with the *meonanthum* cross, Penacova × Coimbra, and reciprocal, segregated for affected and unaffected plants irrespective of the way the *meonanthum* cross was made. No necrosis was transmitted across the union when grafts were made between affected and unaffected plants. This strongly indicates that the cause is nuclear-genetic, perhaps similar to that of the wheat necrosis[6], rather than cytoplasmic or of virus origin. Tetraploid *orontium* (Kew) showed a few slight stem-lesions but no necrotic spots. No necrosis or lesions were observed in any of the tetraploid *meonanthum* material.

From Table 1 it can be seen that the production of lesions and necrotic spotting varies characteristically among the different *orontium* × *meonanthum* crosses. As there is a characteristic siting of necrosis, according to the cross, the condition cannot be attributed to haphazard breakdown of tissue; the differential siting and degree of breakdown would seem to be an expression of associations of complementary genes variously carried in some populations that have, in these hybrids, come together in unbalanced genomes. Different degrees of additional gross unfitness in a wide cross may, therefore, result from latent complementary genetic differences between parents that only show in particular F_1's and which can be variously contributed by either male or female parent. Such genes could be carried in populations without any rigorous erosion as they are apparently expressed only in this very rare cross which, being sterile, has no mating continuum.

Frequency of Quadrivalents in Autotetraploid Plants

The cytological examination of chromosomes at meiosis in autotetraploid plants is an important part of the study of chromosome behaviour. Cytological studies have varied in intensity from casual observations at meiosis to meticulous analyses of all configurations observable, including an estimate of the frequency of quadrivalent formation. It is a common belief that the number of quadrivalents formed is governed by: (1) the size of the chromosomes; (2) the chiasma frequency; (3) the existence of

Table 1. ASSOCIATION OF CHROMOSOMES AT FIRST METAPHASE IN SOME AUTOTETRAPLOIDS

Species	No. of chromosomes	No. of cells	Univalents	Bivalents	Trivalents	Quadrivalents	Percentage of chromosomes in quadrivalents
Plants with large chromosomes							
Lilium, garden hybrid	48	50	< 0·1	5·0 (0–10)	< 0·1	9·4 (7–12)	78·3
Triticum durum	56	100	1·2	8·9 (2–18)	0·5	8·8 (6–13)	62·8
Avena strigosa	28	50	< 0·1	5·9 (0–10)	< 0·1	4·0 (1–7)	57·1
Medium to small chromosomes							
Asparagus officinalis	40	25	0·7	5·2 (0–10)	0·4	6·9 (4–10)	69·0
Petunia hybrida	28	10	0·1	4·6 (2–8)	0·1	4·6 (2–6)	65·7
Small chromosomes							
Ageratum houstonianum	40	10	—	7·4 (4–10)	—	6·3 (5–8)	63·0
Lycopersicum esculentum	48	25	< 0·1	9·9 (4–14)	< 0·1	7·0 (5–10)	58·3
Raphanus sativus	36	10	—	5·2 (2–12)	—	6·4 (2–8)	71·1
Antirrhinum majus	32	25	0·1	2·7 (0–8)	0·1	6·5 (4–8)	81·2
Kalanchoe blossfeldiana	68	25	< 0·1	12·5 (8–18)	< 0·1	10·7 (8–13)	62·9
						Mean	66·9

localized rather than random chiasmata; (4) an excess number of chromosomes, within a cell, which prevents the physical process of pairing; and (5) genetical control. Several of these factors have been discussed under different aspects, sometimes with a slight change in meaning. For example, the cause of low quadrivalent formation has been related to the paucity of 'pairing blocks', the position of the centromeres in chromosomes, and chiasma interference across the centromere[1].

We recently completed a study of meiosis in seven autotetraploid cereals and grasses in which we were not able to demonstrate major differences between the species in regard to the number of quadrivalents that were formed[2]. All strains or species had $4x = 28$ chromosomes and a mean of 4·3 quadrivalents. That is, about two-thirds of the chromosomes were united as quadrivalents. Similar proportions of chromosomes were associated as quadrivalents in autotetraploid flax ($4x = 60$) and corn ($4x = 40$). Both these species have small chromosomes. A further test with a wider range of material was immediately suggested because our results obviously did not conform to current concepts of quadrivalent formation in autotetraploids.

Meiosis was studied in ten different autotetraploids, representing a wide range in plant types, chromosome number and size. The species (Table 1) have been arranged in decreasing order of nuclear size (see also Fig. 1). It is immediately evident that in plants with small chromosomes as many quadrivalents are formed as in plants with large chromosomes. The results also support our hypothesis that in all autotetraploids, approximately two-thirds of the chromosomes form quadrivalents.

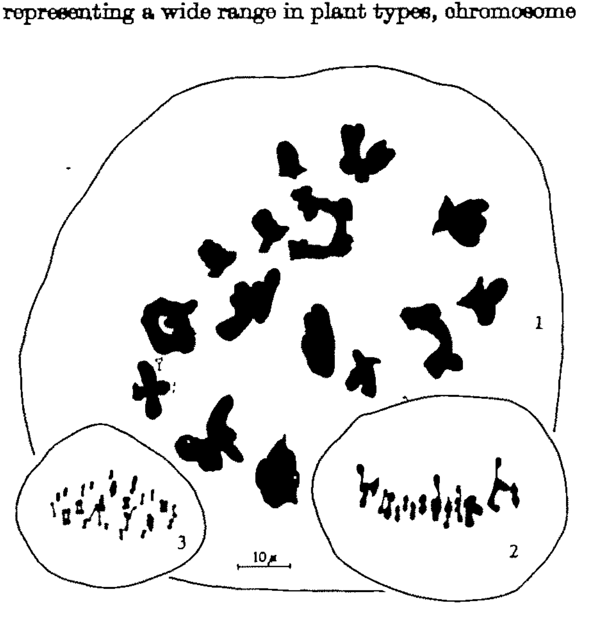

Fig. 1. Cells at first metaphase of meiosis. 1, *Lilium* $6^{II}9^{IV}$; 2, *Asparagus* $8^{II}6^{IV}$ (4 large, 2 small); 3, *Kalanchoe* $14^{II}10^{IV}$

Table 2. ASSOCIATION OF THE FOUR SMALL AND THE SIX LARGE CHROMOSOMES OF *Asparagus officinalis* IN 25 POLLEN MOTHER CELLS

Associations	Small chromosomes		Large chromosomes	
	Average number	Percentage of total possible	Average number	Percentage of total possible
Univalents	0·3	1·8	0·4	1·6
Bivalents	2·4	31·0	2·8	23·3
Trivalents	0·1	1·8	0·3	3·7
Quadrivalents	2·6	65·0	4·3	71·6

Several examples in plants[3] and in animals[4] have been cited to show that within an organism the larger chromosomes form more quadrivalents than the smaller. We found that in the tetraploid *Asparagus* the small chromosomes formed as many quadrivalents as the large ones (Table 2). Our results for *Asparagus* do not nullify previous reports. But when this evidence is considered in conjunction with the fact that in very small chromosomes of *Kalanchoe*—so small in fact that chiasmata cannot be estimated—there is no restriction of quadrivalent formation, then it seems reasonable to suppose that size alone does not limit the formation of quadrivalents: the shortest chromosomes are long enough to undergo the reactions necessary to produce quadrivalents. Because our results do not uphold the assumption that plants with small chromosomes have fewer quadrivalents than plants with large chromosomes we therefore disagree with the conclusions of Kostoff[3] and see no reason why autotetraploids with small chromosomes should be more suitable for plant breeding than those with large chromosomes.

If only one chiasma is formed between two chromosomes in a bivalent then, under our present concepts of chromosome behaviour, no quadrivalents would be possible in a homologous set of four chromosomes. It follows that if a species had a low chiasma frequency per bivalent, fewer quadrivalents would be formed. To be of any value in clarifying the problem a chiasma count would have to be made at the actual time of union or crossing-over. With present-day techniques this is not feasible and the later stages, diakinesis or metaphase, are used. Chiasma number of the diploid *Lilium* has been estimated at 3–5 per bivalent, in *Triticum* and *Avena* at 2–3, in *Lycopersicum* at 1–2 and a similar low figure for other small chromosomes. It is quite impractical to estimate chiasma number for small chromosomes and counts given for some can be viewed with considerable circumspection. We found a fairly uniform number of quadrivalents for all the species and so conclude that either the present-day estimates of chiasmata are out of line or else frequency has no effect on the number of quadrivalents formed.

Localization is difficult to detect by cytological methods and is often assumed to be the rule in organisms when terminalization does not occur. It is undetectable in cytological preparations of small chromosomes and therefore our results do not add much evidence. If localization is a true phenomenon and not an artefact arising from our inability to trace chiasmata in cytological preparations, then, coupled with low frequency of the event, it would probably restrict quadrivalent formation. However, because it holds only for special species and is not constant under all conditions, it should not be regarded as exercising major control over quadrivalent formation.

The implication that physical interference could restrict quadrivalent formation is a direct one relating comparative nuclear volume to the number of chromosomes within that nucleus. The diameters of the nuclei at pachytene varied from 45μ in *Lilium* to less than 15μ for *Lycopersicum* and *Kalanchoe*. The chromosome numbers ranged from 28 to 68. Yet, in none of the species studied was there any indication that crowding of the chromosomes had restricted quadrivalent frequency.

Some cytologists still support the theory that a trend towards 'bivalency' occurs in autotetraploids. We do not, because in advanced generations of many different induced autotetraploids we did not find any reduction in quadrivalent frequency. Further, in the natural autotetraploids *Hordeum bulbosum*, *Hordeum violaceum*, and *Arrhenatherum elatius* we found no evidence for an increase in the number of bivalents[3]. In this study of ten autotetraploids, representing different families and orders, approximately two-thirds of the chromosomes formed quadrivalents. This does not deny the existence of a gene which could control quadrivalent frequency, but it does give some warning against the acceptance as autotetraploids of those plants with twice the expected number of chromosomes in which no quadrivalents are found, for example, in the supposedly clear-cut case of autopolyploidy, *Galax aphylla*[6]. Our results, then, show no evidence of gene control over quadrivalent frequency and support the hypothesis that the behaviour is similar for all species.

OCEANOGRAPHY

Southern Atmospheric Cyclones and the Whale Feeding Grounds in the Antarctic

KNOWLEDGE of the distribution of the stocks of commercial fishes and whales is of no less interest than knowledge of their numbers. N. A. Mackintosh[1] suggested that "it may be that since Blue and Fin whales tend to concentrate in much the same regions in the Antarctic [where the Humpbacks concentrate —C. W. B.], they too, although they do not crowd into temperate coastal waters, are still loosely influenced by the southern land-masses, and that it is subsidiary features of their distribution that are controlled by their immediate environment" (p. 259). This communication gives a possible explanation of this "loose influence".

After their arrival in the Antarctic the whalebone whales start seeking their food (mainly krill, *Euphausia superba*) at random. Nevertheless, in spite of their random movements, the whales are grouped in separate areas, approximately 20–60° long. from each other. These areas correspond to the well-known whaling grounds situated one in each of the whaling sectors, outside the former sanctuary[1]. The uneven distribution of the whales is an obvious result of the uneven distribution of the krill (see maps). The krill itself is influenced by the atmospheric cyclones in a following way[4].

Due to atmospheric cyclones, the Antarctic Divergence is not continuous but is formed of areas where the water rises very intensively in the centres of the cyclones and of areas where it sinks in their peripheries[4]. The longer the cyclone stays in a given place the more intensive upwelling it induces near its centre. In the zone of the Antarctic Divergence in the centres of cyclones the upwelling is easily noticeable by the increased area between the isotherms 1·5° C. and

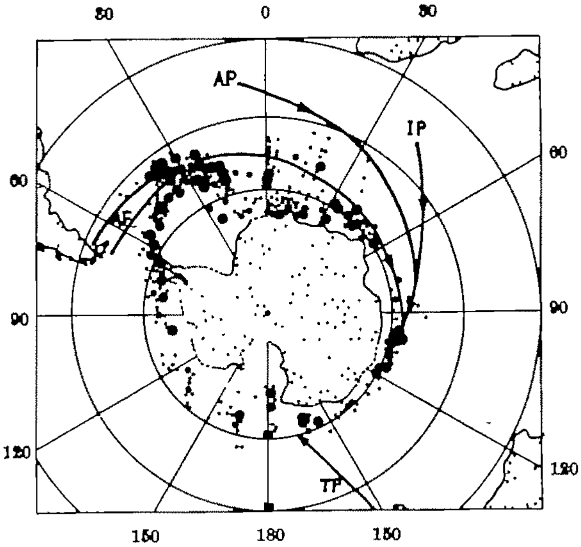

Fig. 1. Krill and cyclones distribution in the Antarctic (combined from Marr (ref. 2), Tauber (ref. 10) and Schmitt (ref. 12). with modifications). Arrows, tracks of cyclones in January; *AP*, cyclones of the Atlantic polar front; *IP*, cyclones of the Indian polar front; *TP*, cyclones of the Tasman polar front; *AF*, cyclones of the Antarctic front; circles, quantity of *Euphausia superba* not less than 20 mm. long, based on the catches of 1 m diameter stramin nets towed on the surface during the pelagic whaling season, January–February–March. ·, 1–100; ●, 100–1,000; ●, 1,000–10,000; ○, 10,000–100,000

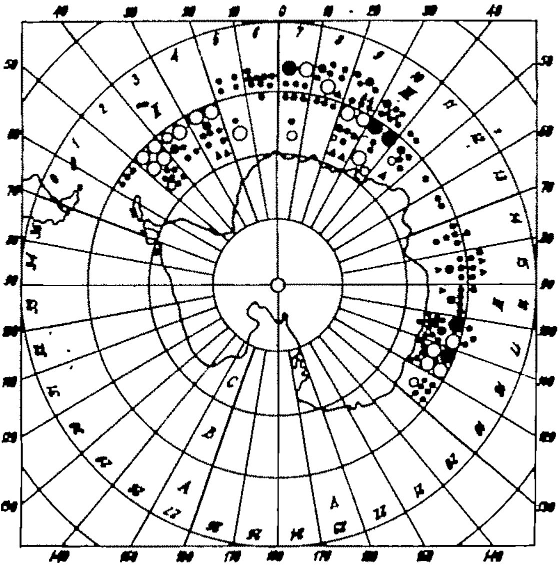

Fig. 2. Number of whales killed during the pelagic season 1937–38 (after Zenkovich (ref. 3)). Black circles, blue whales; open circles, fin whales (large circles, 1,000; medium circles, 500; small circles, 100); open triangles, humpbacks (100). In different years the maxima of whales are not situated exactly at the same places

2·0° C. in the layer of maximal temperatures[4]. The barren upwelled 'new water' carries along the phytoplankton cells to the peripheral region of the cyclone, thus forming a 'clearing' in the diatom bloom. At the same time the upwelling adds to the rise to the surface of the later *Furcilia* larvæ and young adolescent krill[4] which lives in its earlier stages in the intermediate warm water layer[7]. A similar distribution pattern of phytoplankton and euphausiids (*Euphausia pacifica*) can be seen in the Monterey Bay (California) area[8], where a canyon acts as a fountainhead from which the cold waters rise and then spread out to other regions of the Bay. During the upwelled-water period there is a 'clearing' in the bloom over the canyon and tremendous swarms of *E. pacifica* have been observed at the surface in broad day-light there, though normally this species is found near California coasts at depths of 100–400 m.[8], in the intermediate water layer of sub-arctic origin[9]. (It must be remembered that the phytoplankton distribution is never operative in the distribution of krill and whales, but the 'clearings' are very characteristic features of the local upwelling areas and thus worth mentioning.)

In the eastern hemisphere the cyclones of the antarctic front have their maximal frequency between 0° and 70° E. Near the coasts of Antarctica the cyclones of the polar front have their maxima at 90–110° E., 140–170° E., and in the Ross Sea. The number of the cyclones diminishes eastward and is minimal in the southern Pacific[10] (Fig. 1).

The krill is more abundant, and there are more blue and humpback whales in regions where the cyclones are more frequent and stay longer. The centres of these regions are situated at 35° E., 95° E., and 175° W. The total amount of the krill and of the blue whales killed per annum (like the cyclones) diminish eastward and are minimal in the southern Pacific.

In the mean the feeding grounds of fin whales are situated more northerly than those of the blue whales, and therefore the former feed mainly on larger older developmental stages of the krill which are not so closely connected with the areas of the upwelling in the zone of the Antarctic Divergence as the small 'blue whale krill'[1,2,11]. The fin whales are more uniformly distributed in antarctic waters than the blue and humpback whales are and are more loosely connected with the atmospheric cyclones.

The cyclones of the polar front are formed in the sub-tropical zone in the regions of the hydrological fronts between the warm and cold currents to the east of the southern parts of America, Africa and Australia. From these regions they migrate to the south-east and enter the antarctic zone[10,12]. In consequence there are more polar-front cyclones where the continents lie more closely to each other, that is, in the Atlantic and Indian sectors. The position of individual regions rich in krill and whales is largely determined not only by the local antarctic conditions but also by the tracks of the polar front cyclones as well. Thus the distribution of the most important pelagic animals in the Antarctic is influenced by the general distribution of sea and land in the southern hemisphere. The cyclones of the polar front promote the spreading of the influence of sub-tropical land-masses in the antarctic zone.

PSYCHOLOGY

Time Uncertainty and Choice Reaction Time

The duration of the foreperiod, that is, the interval between some warning signal and the stimulus, has long since been known as one of the main factors which influence the length of simple reaction time[1–4]. Klemmer[1] has recently shown that reaction time is shorter with brief (0·25 sec.) constant foreperiods than with either longer constant foreperiods or variable ones. He suggested that the critical factor is 'time uncertainty', that is, uncertainty as to the moment of occurrence of the stimulus. This uncertainty would result from the length of the foreperiod as well as from its objective variability, due to the inaccuracy of internal time estimation processes. Speed of reaction clearly depends on the possibility for some transitory state of preparation to be reached at the right time.

In the case of simple reactions, the only limit to speed comes from time uncertainty. In the case of choice reactions, there is also uncertainty as to the nature of the stimulus to come and consequently of the response to be given. We were interested to know whether the usual effects of time uncertainty can then still be observed. An answer to this question could throw some additional light on the nature of 'preparation', by telling whether it is a completely selective process, linked to a particular stimulus-response pair. If preparation is completely selective, it is of no use to be able to anticipate the moment of occurrence of the signal if one does not know which it shall be. Then choice reaction time, provided the series of signals is non-redundant, must be independent of foreperiod variability. If it is not, some degree of non-specific preparation must be possible.

The exploratory experiment to be reported consisted of measuring both simple and choice reaction time under conditions (*a*) of constant short foreperiods of 0·50 sec., (*b*) of variable foreperiods, 8 intervals ranging by roughly equal steps from 0·25 to 5·50 sec. appearing in random order with equal frequencies. A neon bulb provided the warning signal. On every trial, it was lighted for 2·5 sec. The foreperiod started when it went off. The stimulus itself was provided by a cold cathode indicator tube, with figure-shaped coils (a 'Nixie' tube, manufactured by the Burrough Corp.). For the choice reactions, the stimuli were a 4 or a 3, and two relays served as response keys, which the subjects pressed with both index fingers. For the simple reactions, the stimulus was a 3 and the subject responded with the right index. 5 per cent of catch-tests were interspersed, to discourage premature reactions. The duration of the foreperiod was controlled by a capacitance-resistance circuit. Reaction times were measured to the nearest 0·01 sec. with a chronoscope.

Four subjects participated in 14 sessions—6 practice and 8 experimental. One session consisted of 200 trials. During the experimental sessions, the four conditions were alternated in balanced order, two conditions being given on each session. For each condition, we have thus 4 series of 100 measurements. The first 20 in each series were discarded.

The average reaction times per subject and per condition are given in Table 1. The differences between related means for constant and variable foreperiods were tested, using the t test. For simple reaction times, 3 subjects respond faster with constant foreperiods, as expected. Subject 4 paradoxically gives the inverse result. In the last 4 practice sessions, however, this subject gave shorter reaction times ($m = 236$ m.sec.) with constant than with variable ($m = 267$ m.sec.) foreperiods; but later, for some unknown reason, responded considerably more slowly in the constant foreperiod condition.

Table 1

Condition	Reaction	Foreperiods	Score	Subjects			
				1	2	3	4
1	Simple	Constant	*R.T.* (m.sec.)	212	240	201	254
2	Simple	Variable	*R.T.* (m.sec.)	260	282	241	248
			t (2 − 1)	16·7†	14·5†	18·8†	−2·9*
3	Choice	Constant	*R.T.* (m.sec.)	361	360	350	334
4	Choice	Variable	*R.T.* (m.sec.)	381	422	382	368
			t (4 − 3)	5·7†	12·5†	6·2†	9·8†
3	Choice	Constant	errors (per cent)	1·2	1·6	1·2	1·9
4	Choice	Variable	errors (per cent)	2·2	2·5	0·9	1·8

* $P < 0·01$. †, $P < 0·001$. *R.T.*, reaction time.

The main result, however, is that, for each subject, variable foreperiods give rise to considerably longer choice reaction times than constant ones. Some efficient preparation can still be done when the nature of the response to be given is unknown. It seems thus that preparation is not a completely selective process.

In this experiment, time uncertainty in the variable foreperiod conditions can be a result of longer average foreperiod as well as of variability. A more extensive experiment is being carried out, where both parameters are varied separately, and will be reported later.

The Relativity of 'Meaning'

IT is now widely accepted that the information content of a message is not intrinsic to the message: it depends on the set of messages from which the message comes. Not so generally accepted is the postulate that the meaning of a message also depends on the set that the message comes from. The following example, though imaginary and seeming flippant, shows decisively that the presence of another message may grossly affect the meaning of what is transmitted, though the other message is in fact not sent.

The story is told that Mr. and Mrs. A, while on holiday, decided to send a greeting back to the wife's mother. The telegraph company offered a set of standardized messages (actually only two), which were:

Message 1: "How we wish you were here!"
Message 2: "The weather is fine."

In fact they sent message 1 to express a simple and friendly meaning.

Suppose, however, that the company had also offered:

Message 3: "Do come and join us!"

In its presence, the message "How we wish you were here" becomes merely ironic; for to send it is equivalent to a refusal to send the invitation.

Thus, in this example at least, the 'meaning' of message 1 is not intrinsic to the actual words sent: it is a function of the whole set. Passing from the message to the meaning thus resembles such functional operations as taking the average, or the maximal value. According to this view, the 'meaning', on the reception of message i from the set $\{1, 2, \ldots, i, \ldots\}$ is not to be identified with the element i but with forming the i-th function over the set of messages. Applied to the brain (as a dynamic system the behaviour or activity of which forms some function of its input) this view suggests that we should relate the 'meaning' not to the message that comes to it as input but to the particular behaviour or output with which the brain responds.

W. ROSS ASHBY

Burden Neurological Institute,
Bristol.

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned.

Physicist (honours graduate), for work concerning dosimetry and related problems in the clinical use of high energy radiation from isotope beam units and, in the near future, a linear accelerator—The Assistant Secretary, Westminster Hospital, London, S.W.1 (August 10).

Hospital Physicist, Basic or Senior grade (with an appropriate science degree), in the Regional Physics Unit, for work concerned with the uses of radiation and radio-isotopes in the diagnosis and treatment of disease and includes co-operation with the medical staff on physical and instrumental problems—The Secretary, Leeds Regional Hospital Board, Park Parade, Harrogate (August 12).

Lecturer (with an honours degree and preferably teaching and/or industrial experience) in the Department of Physics and Mathematics, College of Technology, Byrom Street, Liverpool, to teach, to graduate level, in either mathematics or physics and to intermediate standard in other subjects—The Director of Education, 14 Sir Thomas Street, Liverpool 1 (August 12).

Biochemist (Basic grade)—The Administrator and Secretary, University College Hospital, Gower Street, London, W.C.1 (August 13).

Biochemist, Basic grade (with an honours degree in chemistry, biochemistry or physiology, or Associate or Graduate Member of the Royal Institute of Chemistry) in the Department of Chemical Pathology—The Secretary, The United Liverpool Hospitals, 80 Rodney Street, Liverpool 1 (August 13).

Principal Lecturer (with a high academic or professional qualification, and specialized in one of the following: concrete technology, materials of construction or services) in Applied Science (Building and Civil Engineering)—The Bursar, College of Advanced Technology, Gosta Green, Birmingham 4, quoting "B" (August 13).

Research Fellows in Polymer Chemistry or Polymer Technology, Combustion or High Temperature Materials; Research Fellows and Research Assistants in Physical or Industrial Metallurgy; and a Research Fellow and Research Assistants in Fluctuation, Shot Noise and Flicker Effect, Electron Space Charges, Information Theory Wave Optics or Nuclear Emulsion Studies—The Bursar, College of Advanced Technology, Gosta Green, Birmingham 4, quoting "D" (August 13).

Research Officers (with the research outlook and a degree level knowledge of statistical mathematics) in Operational Research—The Director of Establishment, British Transport Commission, 222 Marylebone Road, London, N.W.1 (August 13).

Lecturers in Physical and in Organic Chemistry at the University of Melbourne—The Registrar, University of Melbourne, Parkville, N.2, Victoria, Australia (August 15).

Research Fellow, to undertake original work in the mathematical fairing of ship lines; and a Research Assistant to prepare and run programmes for routine ship calculations—The Secretary of University Court, The University, Glasgow (August 15).

Senior Physicist (with good general experience of hospital physics) in the Radiotherapeutic Centre—The Secretary, Addenbrooke's Hospital, Cambridge (August 15).

Technician (with experience in metallurgy and elementary workshop practice), to be responsible for work in the metallurgical laboratories and workshop—The Principal, Coventry Technical College, Butts, Coventry (August 15).

Senior Lecturer or Lecturer (honours graduate in electrical engineering or physics and suitable research and teaching experience in electronics and radio communication) in Electrical Engineering—Joint Clerk to the University Court, Queen's College (University of St. Andrews), Dundee (August 20).

Research Chemist (with experience of research work in physical chemistry or chemical engineering, and preferably with a higher degree in one of these subjects), to continue a programme of measurements of the heat capacities and Joule-Thompson coefficients of vapours under the terms of a contract between the University and the D.S.I.R.—The Registrar (Room 22, O.R.B.), The University, Reading (August 22).

Rheumatism Research Fellow (with qualifications or special interests in physiology, or physics, or physical chemistry), for research on tissue elasticity—The Registrar, The University, Leeds 2 (August 22).

Principal Scientific Officer or Senior Scientific Officer (with a first- or second-class honours degree in science with chemistry or physics as the main subject, or equivalent, and at least three years postgraduate or other approved experience, and research experience in the field of organic or physical chemistry) at the British Museum, London, W.C.1, to supervise research in the examination and conservation of antiques and archæological material—The Civil Service Commission, 17 North Audley Street, London, W.1, quoting S/5177/60 (August 23).

Assistant Lecturer in the Department of Physics—The Secretary, Medical College of St. Bartholomew's Hospital, West Smithfield, London, E.C.1 (August 25).

Research Physicist (honours graduate in physics (or equivalent qualifications) and some years postgraduate research experience) at the Irrigation Research Station, Commonwealth Scientific and Industrial Research Organization, Griffith, New South Wales, Australia, to investigate the response of plants to changes in their environment, particularly the phenomena associated with the sudden change of incoming radiation and other energy factors—Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting Appointment No. 500/119 (August 27).

Experimental Officer (with a qualification in electronics, electrical engineering or a relevant branch of physics or chemistry) in the Chemistry Department, to be responsible for the supervision and maintenance of electronic instruments in the Department, especially infra-red and ultra-violet spectrometers—The Registrar, The University, Southampton (August 31).

Research Fellow (Microbiologist, with postgraduate research experience, and preferably experience in microbial genetics) in Microbiology, to join a research team of chemists and microbiologists concerned with fundamental studies on biosynthesis—The Registrar, University College, Singleton Park, Swansea (August 31).

Senior Lecturer and a Lecturer in Botany, and Lecturers (2) in Geography at the University of Melbourne—The Registrar, University of Melbourne, Parkville, N.2, Victoria, Australia (August 31).

Senior Lecturer in Applied Mathematics at the University of Malaya, Singapore—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (August 31).

Senior Lecturer in Educational Psychology at the University of Natal, Durban, South Africa—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (South Africa and London, August 31).

Assistant Lecturer (graduate, with special interests in either igneous petrology or sedimentary petrology and palæozoic stratigraphy) in Geology—The Registrar, The University, Exeter (September 10).

Lecturer (with medical qualifications or higher degree in physiology) in the Department of Physiology, University of the Witwatersrand, Johannesburg, South Africa—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (South Africa and London, September 15).

Principal of the National College of Agricultural Engineering, Silsoe, Bedfordshire—National College of Agricultural Engineering, c/o Ministry of Education, FE(IV)A, Curzon Street, London, W.1 (September 16).

Biochemist (graduate in chemistry, biochemistry or physiology) in the Pathology Department, for work concerned with biochemical investigations on patients—The Group Secretary or Consultant Pathologist, Dulwich Hospital, East Dulwich Grove, London, S.E.22.

Biochemist or Immunologist (preferably with a Ph.D.), for research on the thyroid gland, with particular reference to thyroid auto-immunity—Dr. I. M. Roitt, Middlesex Hospital Medical School, London, W.1.

Biochemist (with an appropriate science degree or the A.R.I.C.) to work under the direction of the Chemical Pathologist at the City Hospital—The Group Secretary, Nottingham No. 2 Hospital Management Committee, Sherwood Hospital, Hucknall Road, Nottingham

Chief Technician I (F.I.M.L.T., or equivalent qualification) in the Department of Histopathology, to maintain the efficient running of the Department and to train Junior Staff—The Secretary, Royal Free Hospital, Gray's Inn Road, London, W.C.1

Experimental Officers and Assistant Experimental Officers (with H.S.C. or G.C.E. or equivalent, or H.N.C. or university degree) in Mathematics, Physics, Meteorology, Chemistry, Metallurgy, Biological Sciences, Engineering, Miscellaneous (Geology, Library and Technical Information Services)—The Civil Service Commission, 17 North Audley Street, London, W.1, quoting S/94-96/60.

Geneticist, Principal Scientific Officer/Senior Scientific Officer (with a Ph.D. or good honours degree, and at least two years postgraduate research experience in microbiology), to take over the Genetics Section—The Secretary, Research Institute (Animal Virus Diseases), Pirbright, Surrey.

Laboratory Technician (preferably with experience in animal keeping) for Biology at L.C.C. Furzedown College—The Secretary, Furzedown College, Welham Road, London, S.W.17, quoting (Estab. 7/N/1952/7).

Lecturer (chemical or mechanical engineer, or metallurgist) in the Department of Metallurgy, to teach basic engineering aspects of extraction metallurgy, including effects of heat, mass and momentum transfer on the design and operation of processes—Prof. F. D. Richardson, Department of Metallurgy, Imperial College of Science and Technology, Prince Consort Road, London, S.W.7.

Medical Laboratory Technician (with experience in biological, immunological or microchemical assays)—Dr. R. G. Macfarlane, Blood Coagulation Research Unit, Churchill Hospital, Oxford.

Power Station Chemists (qualified and experienced chemists), for the Power Stations of the Electricity Supply Commission in the Transvaal and Orange Free States, South Africa—The London Representative, Electricity Supply Commission, 723/737 The Adelphi, John Adam Street, London, W.C.2, quoting Ref. E/263/4

Research Assistant (with a first- or second-class honours degree in biochemistry), to assist with investigations into disturbances of calcium metabolism in man—The Director, Metabolic Disturbances in Surgery Research Unit, The General Infirmary, Leeds.

Scientific Director (with three years postdoctoral research experience in nuclear reactions) of the Nuclear Physics Laboratory of the Institute of Physics and Mathematics, to lead research around an operating 800 kV. Cockcroft–Walton accelerator and to lecture on experimental and theoretical nuclear physics at the School of Physics of the University of Chile—Director, Instituto de Fisica y Matematicas, Universidad de Chile, Casilla 2777, Santiago, Chile

Scientific Officer (honours graduate in chemistry or biochemistry) in the Radiobiochemistry Department, for biochemical research involving the use of radioactive isotopes and in particular C^{14} and tritium—The Secretary, National Institute for Research in Dairying, Shinfield, Reading, quoting Ref. 60/3.

Senior Scientific Officers/Scientific Officers (with a first- or second-class honours degree or equivalent in an appropriate subject), in the Traffic and Safety Division, Road Research Laboratory, Langley, Bucks, to carry out theoretical and experimental research on traffic flow and road safety, including psychological aspects, physics of friction and impact problems, and the relationship between vehicle design and injuries sustained in road accidents—The Ministry of Labour, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting A.286/0A.

Soil Physicist (with training in modern techniques and preferably with experience of the irrigation of heavy clays) with the Kafue Pilot Polder Trust in Northern Rhodesia—The Personnel Officer, Rhodesian Selection Trust, P.O. Box 1479, Salisbury, Southern Rhodesia.

Visiting Assistant Professor–Research Associate, to give some lectures in general chemistry and in an advanced course in inorganic chemistry, help with the supervision of laboratory work and engage in research in inorganic chemical synthesis or reactions—Louis J. Bircher, Box 1550, Vanderbilt University, Nashville 5, Tennessee, U.S.A.

ZOOLOGIST (ENTOMOLOGY) (with a degree in general biology, biology or entomology) with the Government of Kenya, to work in the laboratory or field principally on insect vectors and possibly other parasitic diseases of animals—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD.67/7/010.

MANAGERIAL RESOURCES: AN INTERNATIONAL SURVEY

SOME reasons for Britain's continuing difficulties with her balance-of-payment problems have been revealed in three recently published works. An American book presents an international picture of management in a number of industrialized countries[1]. A British book deals particularly with the management scene in Britain[2]. The third is a comparative study by an American don who has looked critically at American and Russian industry and, after a year as a Fulbright Scholar in Britain, has produced a book which points to the inescapable conclusion that British industry will remain hamstrung until there is a marked improvement all round in the quality of her executives.

The seesaw of import–export figures with every other year producing too little to cover long-term overseas investments has been with us since the War. Exhortation for more productivity to give us more exports has led up to the fourth balance-of-payments crisis during the past decade and has once more caused the Chancellor of the Exchequer to apply the brakes to industrial investment. The overall result has been a slow rise in British productivity which has been insufficient to pay for our imports, the improved standard of living which should accompany productivity, and to leave enough for essential overseas investment. The tragedy for Britain is that other European countries have been able to steer clear of balance-of-payment difficulties. An authority like Colin Clark has confirmed that increases in productivity of most industrialized countries have exceeded those of the United Kingdom[4]. The rise over the past year has still not been enough to prevent the Chancellor calling a halt to expansion.

Many of our difficulties lie, of course, within the political, economic and social fields. But from Harbison and Myers's analysis of management in the industrial world, a considerable part of our trouble is bound up with the quality and distribution of men occupying top and middle management positions in our industrial organizations.

Harbison and Myers first define the bases on which their comparisons of management are made, and then, with expert help from various countries, go on to examine the nature of management as an economic resource, as a system of authority and as a class, as well as the development of managerial resources in different industrialized countries.

Compared with countries like India, Egypt, Chile and Israel, which are less developed industrially, Britain, in common with other advanced industrial nations like Japan, Germany, Sweden, the U.S.S.R. and the United States, possesses reserves of actual and potential management talent which helps them to maintain their industrial supremacy. That this position is not likely to go without challenge is shown by Egypt, where institutions for the generation of high-talent man-power are quite advanced. In contrast to France, Italy and many of the newly developing countries, Egypt's industrial progress is not retarded by a conservative patrimonial *élite* and its managers . . . "are receptive to new ideas". Despite the warnings and forebodings of British politicians, for example, in 1958 the all-Egyptian management of the Suez Canal Authority was handling 25 per cent more ship traffic than "its predecessor foreign management handled before 1956. At the same time, the total number of white-collar, technical, professional and managerial positions has been reduced by 23 per cent". In Israel, a vigorous, young and aggressive managerial class has sprung up with growing social prestige.

For Britain, management comparisons with other advanced industrial countries are more revealing. In Japan, concentration of industrial power in the hands of the *zaibatsu* has led to the remarkable development of human resources in general and high-talent man-power in particular. The vast industrial empires of the *zaibatsu*, motivated by a nationalistic patriotism, have been successful in building managements which are imbued with the spirit of hard work, perseverance and unfaltering loyalty both to the organization and the dynasty which controls it. In the larger firms there is an almost feverish interest in new techniques, and to-day Japan is probably one of the few countries which could easily export high-level man-power resources without straining its economy; entry into the ranks of professional management is based primarily upon formal education.

The West German achievement is well known; there is no adequate parallel to the transformation of West Germany since the War. Between 1950 and 1957 the gross national product was more than doubled; the British increased slightly.

Like his counterparts in the United States, the U.S.S.R. and Japan, on the solid basis of prestige, power and wealth, the German manager vies for prominence among the members of other high-status groups. A significant difference between the German system and the British is that, in Germany, the top-level man, the *Unternehmer*, has real authority and direct interest in the business he controls, and is so free from day-to-day executive activities that he is able to forecast, plan and direct the policy of the company. Few boards of directors in Britain are able to function in this way, although our system of having a good sprinkling of executive directors has much to commend it.

The great difference between German, Russian and American management and that of the United Kingdom lies in the educational background of the men and women who become managers. In 1955, for example, at least 31 per cent of German top management had university degrees; the largest single group consisted of graduates from the *Technische Hochschulen*. The position is much the same in the United States and the U.S.S.R. In the U.S.S.R. the change has been from a peasant, agrarian economy to a high level of industrial achievement since the introduction of the first five-year plan three decades ago. This has not entirely been due to the extreme use of totalitarian methods, concentration on heavy industry and the sacrifice of short-run consumption to facilitate the investment needed for long-term development. The main emphasis in the Soviet Union during the period has been on the development of well-qualified management[4]; the economic results are well known. If nothing else, the Soviet experience provides strong support for the belief that industrialization requires that access to important managerial positions be based on objective standards of competence rather than 'connexions'. Even in their doldrum days of the '30's, the Soviet leaders showed their long-sightedness in insisting that the British, German and American 'foreigners' should be used for training their own men for the future rather than producing results at the time.

The American position needs little underlining; the proportion of personnel of high talent among American management is the highest in the world. In contrast to much of British industry, competence and performance on the job have become the tests by which men are judged, although these reflect not only innate capacities but also prior education; between 50 and 60 per cent of executives have university degrees; and, because of the status which management enjoys in social and economic life, the recruitment of talented young men destined for managerial positions is easier than in most countries. A major difference between American and most other industrialized countries is in the emphasis she has given to the teaching of management subjects in her business-administration schools. Formerly, these were mainly concerned with provision for undergraduates. Since the Second World War, fifty colleges and universities have developed full-time postgraduate courses for industrial executives. Although some of the work done in these postgraduate schools might be rated as shoddy, Prof. Norman Hunt, of the University of Edinburgh, has written that "work of the highest quality both in research and teaching is being undertaken: much of it would stand up to the scrutiny of the most critical of us". The fine work being done in business-training schools is complemented by executive development programmes inside industrial organizations themselves. There is little doubt that American managers are, at present, the best trained in the world. Has this some connexion with productivity?

The British position has been admirably described by McGivering, Matthews and Scott[5], and, although their conclusions must be treated with some reserve, the impression they create does not lead to the belief that Britain can hope, in the near future, to match the examples of Japan, West Germany, the U.S.S.R. and the United States in their drives for productivity.

There are a number of reasons for British weaknesses and difficulties. It is now well established, for example, that the higher the degree of mechanization and the more sophisticated the environment in an industrial organization, the higher will be the ratio of managers required. This is necessarily accompanied by increasing specialization without automatically increasing the overall size of the organization; as Joan Woodward has indicated, "*specialization* technology rather than size *per se* is most important in promoting specialization within management"[6]. Because they find it difficult to see the place of the specialist and because they fear his challenge in the struggle for promotion, many senior executives have done their utmost to resist specialization albeit to the detriment of their companies.

Other factors tend to maintain centralized authority and control. "Firms which are owned by families, or in which the major share-holding interest is held by some other single group, are notoriously loth to expand", if this would lead to any loss of control or delegation of authority. Delegation, too, with all its advantages, can be achieved with greater confidence when adequate measures of the delegates' performance exists. "British management . . . is backward in the employment of techniques of work measurement, cost accountancy and budgetary control." There is also a deep-rooted belief among many senior executives that the higher management skills and especially those which go with 'leadership' are qualities which they possess but are denied to their subordinates; they are believed to accompany a public school education.

There are also factors to indicate that British industry continues to suffer because of social distinctions. Evidence is accumulating that "the rank order of advantageous categories . . . shows the superiority of an Arts degree (Oxon. or Cantab.) or major public school education over an Arts degree (Redbrick) or lesser public school or grammar school attendance". One investigation has shown that there is a direct correlation between social origin and salary; consciousness of social handicaps appear to be more prevalent in family firms and in firms recruiting largely from universities.

A major weakness is in the attitude of many managers towards productivity itself. In Great Britain productivity has frequently been interpreted as low-cost production to yield high returns on a steady market. American companies with manufacturing units in Europe have been quick to exploit their national habit of driving existing plants to achieve greater output without sacrificing quality or increasing costs; Britain has been slow to copy them.

Unfortunately, too, and this may be bound up with the social class background of many British senior executives, the trade unions are still regarded as enemies who must always be fought; the trade unions have responded to the attack, and the joint enterprise of American management and labour for increased productivity with sharing of rewards has not been repeated to the same extent in Britain.

How, then, can Britain hope to achieve a standard of productivity which will enable her to sell exports increasingly in direct competition with other advanced industrialized nations? The quality of management must be raised by increasing the standard of the recruits. Graduates must be used, and more scientists and technologists must command influential positions in the board room. Standards must be set against which performance can be judged. Men must be selected for their competence and not for their social background; there is little doubt that the talents of Great Britain are not being fully used, and perpetuation of the existing class system could lead to national disaster. Training schemes in firms must be developed to produce executives capable of making decisions as well as technicians and craftsmen to support them. Active trade unions should be encouraged to help in the drive for productivity. Above all, the supply of scientists and technologists must be stepped up; a heavy burden rests upon the Ministry of Education and local authorities.

All this will be vitiated, however, unless public opinion outside and inside industry drops its complacency and builds up a climate of opinion in which young men of talent can be given opportunities for making an attempt to raise productivity to standards not yet contemplated. Until this occurs, we can expect to have balance-of-payment difficulties with continuing regularity.

NEWTON'S CORRESPONDENCE

The Correspondence of Isaac Newton

Edited by Prof. H. W. Turnbull. Vol. 1: 1661–1675. Pp. xxxvii+468+7 plates. (Cambridge: At the University Press, 1959. Published for the Royal Society.) 147*s.* net.

THE publication of the first volume of a critical edition of Newton's correspondence is an important event in the domain of history of science. Few periods in the development of human culture offer a more instructive and fascinating field of study than that which saw the birth of modern science. The basic data for such a study, in the form of letters and manuscripts as well as printed books and papers, exist in great abundance, and allow one—especially the letters, with their more personal and intimate communications—to form a vivid picture of the pioneers' adventurous exploration of Nature and of their struggle for the vindication of rational thinking and the establishment of proper methods of scientific analysis. Much of this material has long been available to scholars, above all in the monumental editions of the works and correspondence of Galilei, Descartes and Huygens. In this connexion, the insufficiency of the existing edition of Leibniz's scientific papers, but still more the lack of any coherent publication of Newton's works, has always been felt as a most serious inconvenience, which is still to this day hampering a really exhaustive investigation of some of the most critical phases in this momentous development.

On the Continent, the task of editing the works of great men is regarded as an undertaking of national concern, deserving the support of the Government as well as that of private bodies and institutions. The traditional aloofness of the British Government with respect to cultural matters has had no small part in the long neglect suffered by the Newton papers; but, without unkindness to a venerable institution, it must be said that the Royal Society was also very late in awakening to its responsibility. Prof. E. N. da C. Andrade's introduction to the present volume, in reciting the story of the Society's handling of the matter over many years, has a sad tale to tell of procrastination and inefficiency. Even now, when a most auspicious start has at last been made, our satisfaction is tempered by the disappointing confession that the Society does not feel able to undertake more than the publication of the correspondence; for a critical edition of Newton's great books and of his numerous and still incompletely surveyed manuscript notes and papers, scholars with the necessary leisure and competence, according to Prof. Andrade, are not to be found. In making this excuse he seems to lose sight of the vigorous growth of the modern school of scientific historians; anyhow, it is happily belied by the fact that at this moment, in the United States, two distinguished historians are actually preparing a critical edition of the "Principia", while the study of Newton's unpublished papers is also being actively pursued.

The time is not for incrimination, however, when we are presented with such a splendid achievement as this publication of Newton's correspondence; if the further volumes keep the same high standard, a monument of scholarship rivalling those recalled above will have been raised to Newton's memory. In fact, we are given more than just the letters: partly to atone for the renunciation to edit all the manuscripts, a selection of the latter, namely, those more closely connected with the correspondence, is also included. All texts are accompanied, in conformity with the exacting requirements of modern historical criticism, by the relevant information about their nature and provenance, and by abundant notes elucidating their contents. As regards the latter, some minor blemishes are inescapable—I hope to publish elsewhere a list of the corrections and additions which I noticed during the perusal of the volume—but on the whole the notes are excellent, especially on matters of mathematics and optics. The only serious shortcoming is the lack of accurate bibliographical descriptions of the books quoted (for example, in the form adopted in the Huygens edition); this desideratum could perhaps still be fulfilled in the future volumes. For the accuracy of the text, we must of course trust the editors, and we have certainly no reason not to do so: on internal evidence I have only detected two trifling textual errors (in French texts). The historians of science are indeed deeply indebted to Prof. H. W. Turnbull and his collaborators, the late Mr. W. H. Robinson and Dr. J. F.

Scott, for accomplishing their important task in such a painstaking and skilful fashion.

If we now turn to the contents of this first volume, which covers Newton's youth and his first creative period, during which most of the optical work was done and the new ideas about mathematical analysis and the theory of gravitation took shape, I cannot say that it discloses any striking novelty. Most of the letters and documents had already been published, and the fuller view we now gain by their more complete presentation can only increase our respect for the judgment of the Victorian scholars, Edleston, Rigaud, Brewster, who made the previous selections; it is comforting to realize, in particular, what careful and sagacious use good old Brewster, with all his oddities, could make of his sources. Nevertheless, renewed studies of these sources in their authentic and complete form cannot fail to reveal interesting new details, enlivening the picture of the times and deepening our understanding of the processes of discovery. Especially valuable in the latter respect is the publication of numerous documents illustrating the little-known relations between Newton and Gregory; it is the editor's great merit to have directed attention to them.

Reading such correspondence, in the chronological order in which it is presented, is like listening to a symphony the various themes of which successively appear and interlace, evoking the hero's growth and deeds against the background of his time and environment. In this respect, the comparison of the Huygens and Newton papers during the same span of their lives (three volumes to one!) illustrates in a most telling fashion the difference between the social classes to which they belonged and which supported and influenced their work. Of Newton's rustic youth scarcely any record remains, whereas there is a wealth of documents picturing all the stages of the opulent Huygens children's refined education and their development into sophisticated and slightly snobbish gentlemen. As soon as Huygens's precocious genius shot its first buds, he was admitted with demonstrative honour to the choicest circles of virtuosi; the poor Cambridge scholar had to be content with the less-glamorous, but perhaps more substantial esteem of plain people like himself, engrossed in the business of trade and administration, but compensating the lack of elegance in their intellectual demeanour by seriousness of purpose and a keen sense of reality.

It is highly instructive to watch how John Collins puts young Newton's mathematical skill to the test by proposing to him problems of annuities and related algebraic questions: of such obscure birth is modern analysis! The next theme, recurring through a great part of the volume, is the construction of a reflecting telescope; it is in this work as well as in their mathematical research that Newton and Gregory followed parallel ways, of which they became acquainted through their common correspondent, the always friendly, sometimes officious Collins.

Then comes the dominant feature of the period spanned by the volume under review, the great work on the theory of colours and the nature of light, which is here very fully documented. We may follow in minute detail the famous controversy to which Newton's investigations gave rise, so startling did his new method of reasoning by induction from experiment appear even to men like Huygens and Hooke. However, a careful reading of Hooke's objections, now for the first time available *in extenso* (I allude to the important new document No. 71), reveals that the latter had spotted a real weakness in Newton's argument, namely, his too rigid assertion of the permanent character of the homogeneous coloured rays. In this light, Newton's famous conciliatory letter to Hooke (No. 154), which has hitherto been presented as an example of generosity, cannot fail to strike one, on the contrary, as unpleasantly condescending and arrogant. Without denying Oldenburg's part in embittering the quarrel, one feels that Newton's own obstinacy and unwillingness or incapacity to understand Hooke's point are amply sufficient to account for it.

It is well known that the conception of universal gravitation goes back to the same period of Newton's life, when, as he will later declare, "I was in the prime of my age for invention". Yet, from this time we have only one document (No. 117) of extreme interest, recently brought to light by Dr. A. R. Hall: it is the first appearance of the mightiest theme in the Newtonian symphony, which will unfold itself throughout the further, eagerly awaited instalments of this magnificent publication. L. Rosenfeld

ASTROPHYSICS OF NON-STATIC SYSTEMS

Moving Envelopes of Stars

By Prof. V. V. Sobolev. Translated by Sergei Gaposchkin. Pp. xiv+106. (Cambridge, Mass.: Harvard University Press; London: Oxford University Press, 1960.) 38*s*. net.

THE astrophysicist trying to infer the development of astronomical systems from the available observations is generally like someone trying to imagine the story of a film from a few 'stills' shown outside a cinema. Most astrophysical theory is concerned with such an exercise. However, the astrophysicist is occasionally afforded the advantage of a 'trailer', when he actually sees some change occurring in the heavens as in a nova eruption or in cases of matter obviously streaming away from stars. But a trailer is usually concerned with the more colourful episodes in a story, and a special skill is needed for correctly imagining the whole film from it. The present book is concerned with the analogous exercise in astrophysical theory.

The contents of the book, however, are easy neither to describe nor to assess. This is mainly because, as Prof. Sobolev says, he leaves the general account of the subject to be found in text-books and here presents only his own results, seemingly in much the form in which they were originally published in Russian journals. At any rate, he states the purpose very clearly as "to give a theory of radiative equilibrium of a moving medium and to apply it to the moving envelopes of stars. Because of the breadth of the problem, only the basis of the theory and its most immediate applications are given here".

The account is concise and free from unnecessary complications. In fact, it is so concise that only someone currently working in the field is likely to be able to appreciate its full value. But even someone such as myself whose ventures into the field were some time ago, can realize that Prof. Sobolev has made important advances in the theory and its applications, and that Dr. Gaposchkin has done good service by making them better known by translating them into English. W. H. McCrea

SOUND TRANSMISSION IN THE OCEAN

Introduction to the Theory of Sound Transmission with Application to the Ocean

By C. B. Officer. (McGraw-Hill Series in the Geological Sciences.) Pp. viii+284. (London: McGraw-Hill Publishing Company, Ltd., 1958.) 77*s*. 6*d*.

THE author of this volume is associate professor in the Department of Geology, The Rice Institute, and associate in geophysics, Woods Hole Oceanographic Institution. These facts are mentioned to indicate that the book is of interest not only to physicists who are concerned with sound propagation in the sea, but also to geologists and geophysicists who are concerned with the wider aspects of the subject.

The propagation of sound in the ocean, in shallow seas, and in the Earth beneath the sea has important implications which concern a wide field of science, namely, physics, geophysics and oceanography.

In the preface the author directs attention to the fact that the preparation of the book has been sponsored ("encouraged and supported") by the Office of Naval Research and the U.S. Bureau of Ships, thus indicating its importance to those concerned with the applied aspects of a study of sound propagation in the ocean.

Reference is also made in the preface to many well-known American workers in this field, for example, J. B. Hersey, M. Ewing, J. L. Worzel and others.

The subject-matter of the book is divided into six chapters. The first of these deals with general wave theory for an elastic medium, including the cases of waves of finite amplitude and shock fronts. The second chapter is concerned with the 'ray' and 'normal-mode' theories of sound propagation, with refraction of a dispersive wave-train, and with prescribed boundary conditions. In Chapter 3, these considerations are applied to the case of transmission in shallow water where interference due to multiple surface and bottom images has to be taken into account. The fourth chapter deals with the case of deep oceanic water, where the bottom is not involved. In this case refraction due to temperature and pressure effects on sound-velocity is considered. Chapter 5 is concerned with 'reflectivity' of boundary layers, reflexion from three layers, and the interpretation of echo-sounding records and of geophysical reflexion and refraction profiles. The concluding chapter, "Attenuation", covers absorption in a viscous fluid, scattering and diffraction, and reception by a linear array.

Chapters 3 and 4, which deal respectively with the transmission in shallow water (inshore seas) and in deep water (the oceans), show the difficulties involved in attempting to arrive at a reliable theoretical solution of wave propagation in the sea. Consideration must ultimately be given to many factors, for example, the effects of depth and configuration of the sea-bed, the physical (acoustic) properties of the sea-bed material, the sound-velocity structure of the water (temperature- and pressure-gradients as they influence velocity of propagation), the shape of the sea-surface (waves and swell), the presence of sound-scatterers in the water, and so on. As the author very truly states, "A complete formulation with all possible variations of the above environmental conditions would be very difficult to obtain." The theoretical complications in shallow water transmission due to multiple reflexions between sea-surface and sea-bed are dealt with on both 'ray' and 'mode' theories, but there is clearly much more to be done to predict the sound-distribution in a shallow sea even under the most 'ideal' theoretical conditions of isothermal water and a flat bottom parallel to a flat sea surface.

The problem is a difficult one, and Prof. Officer has made a praiseworthy effort in presenting the theoretical aspect in a stimulating and readable fashion. As an introduction to the subject the book will serve a very useful purpose in arousing interest in physicists, geophysicists and oceanographers alike.

The book is well written, illustrated and produced and can be recommended to all those interested in this difficult but fascinating study of sound transmission in the sea.

A. B. WOOD

THEORY OF HIGH EXPLOSIVES

The Science of High Explosives

By Prof. Melvin A. Cook. (American Chemical Society Monograph Series, No. 139.) Pp. xv+440. (New York: Reinhold Publishing Corporation; London: Chapman and Hall, Ltd., 1958.) 180*s*. net.

THIS book is a valuable addition to the rather sparse literature on the subject of explosives. Its scope is wide; but, as the title suggests, it is concerned more with the basic physical and chemical principles underlying the behaviour of explosives than with practical applications. Nevertheless, there are parts that will be of general interest, in particular the chapters describing the modern explosives industry and the explosion properties and blasting action of high explosives.

Perhaps the heart of the book is formed by those chapters dealing with the mechanism of initiation and propagation of detonation and the accompanying phenomena. Particular attention is paid to the nature of the reaction zone in detonation waves, and the author considers that the classical treatments of Zeldovich, von Neumann, Doering, and others should be modified to include the notion of heat conduction. In addition to claiming that this modification gives a better explanation of the observed distribution of parameters in the reaction zone (for example, the evidence for the existence of a pressure 'spike' predicted by the original theories is inconclusive), he says that it explains what happens to the critical enthalpy that is necessary to initiate detonation. He considers that this enthalpy is contained within the reaction-zone and propagated as a heat pulse. The author claims to have obtained photographic evidence of a heat pulse during the growth to detonation of an initially non-reactive shock-wave in the liquid explosive nitromethane, but unfortunately the features in the original colour photographs to which he ascribes considerable significance do not show up well in the black-and-white reproductions. Also discussed in some detail are the respective theories of non-ideal detonation due to Jones and to Eyring and others. An alternative theory, called the geometrical model, is put forward which asserts that not only must lateral losses, which affect only the equations of continuity, be taken into account but also that only part of the reaction zone lies between the detonation front and the Chapman–Jouguet plane, so that not all the chemical energy released is available for supporting the detonation wave. As mentioned in the book, this theory is essentially the same as that proposed by different authors as long ago as 1928 but not then generally published.

There are useful chapters on the instrumentation used in modern explosives research and on the effects of air and ground blast waves, and considerable space is given to shaped charges and to the behaviour of solids under explosive attack. Perhaps the most disappointing parts of the book are those dealing with the blast waves produced in gases by detonating explosives; no mention is made of the modern approach based on the methods of fluid mechanics and the descriptions are derived from somewhat questionable qualitative assumptions.

The book is not easy to read; in the attempt to be comprehensive there is a tendency in places to deal too briefly with difficult physical concepts and this fault is aggravated by the widespread use of symbols as a shorthand method of writing. Even though the symbols are clearly defined in an appendix it is irritating to have to be continually referring to it. However, it may be said that this is a reference volume for the research worker rather than a textbook, and as such its wealth of detailed information and exhaustive lists of references make its appearance welcome. W. L. MURRAY

STORY OF CHEMICAL INDUSTRY IN BASLE

The Story of Chemical Industry in Basle

Pp. 234. (Published by CIBA Limited on the occasion of its 75th Anniversary.) (Basle: CIBA Limited, 1959.)

THE title of this work is far too modest. In 233 beautifully printed and illustrated pages the history of chemistry is set out in such a way as to give Basle its rightful place in the fields of drugs, plastics, textiles and dyeing. Although Ciba Ltd. are the publishers, full credit has been given to the firms of Sandoz, Geigy, and Hoffmann La Roche, as well as to other firms and individual scientists throughout the world, for their contributions to science and technology.

The first part describes the founding of the first Universities in Paris (by Bartholomew the Englishman in 1231), Oxford, Salerno and Montpellier. The influence of the Guilds is noted as is also the contribution to the Renaissance made by the monasteries. In the fourteenth century the Dominican monastery in Basle possessed works by Avicenna, commentaries on Aristotle, Latin translations of the works of Galen and the medical works of Albert the Great (usually referred to in English books as Albertus Magnus). In 1460 the University of Basle (modelled on those of Paris and Bologna) was founded and eight years later the printing of books commenced in Basle.

The University of Basle received a refreshing blast of fresh air in 1526 when Paracelsus occupied the chair of medicine for a few months. As every student of chemistry knows this rebel publicly burnt the works of Galen and Avicenna and scoffed at the alchemists, stating that medicine, not gold, was the true aim of alchemy.

The story continues to the eighteenth century, and the age of enlightenment. Voltaire, Diderot, Nicholas Leblanc, Edmund Cartwright, James Watt, Adam Smith, Montesquieu and Rousseau are just a few of the famous in all branches of philosophy who appear in the pages of this remarkable book. Next we read how refugees from the Reformation and the counter-Reformation transplanted luxury industries to Basle.

The second part of the book ("The Development of the Chemical Industry in Basle") commences by showing that chemical industry grew from the co-operation between the trade in crude drugs and colouring matters, the apothecaries' shop, and the gas works. In a short history of the ancient drug trade drugs which are also colouring matters (for example, saffron, buckthorn), are mentioned, as well as many others, some of which are illustrated in colour. Surprise is expressed that until the nineteenth century the whole drug was considered essential and no one thought of searching for pure 'active' principles. Extraction of 'principles' soon became commercially popular and in 1857 J. R. Geigy and U. Heusler built a plant in Basle to extract dye-woods. The silk ribbon industry in Basle naturally attracted dyers to the neighbourhood. In 1859, three years after Perkin's discovery of mauveine, Geigy switched his attention to the manufacture of synthetic dyes, starting with the preparation of fuchsine. Also in 1859, Clavel commenced the manufacture of fuchsine in Basle and his firm eventually became Ciba (a name formed from the initial letters of the Society for Chemical Industry in Basle).

The factors leading to the rapid growth in chemical industry in Basle are described. These are briefly (1) the ease with which coal-tar could be obtained from England, France and Germany, (2) the advantage of being able to dispose of waste products in the Rhine, (3) plenty of capital from the older industries, (4) the local market for dyes provided by the silk ribbon industry, (5) the socio-political freedom arising from the unification of the Swiss cantons into a federal State, and (6) the rapid rise in the population (and hence the labour supply) of Basle.

Dyestuffs are next dealt with in some detail, and I have space here only to mention such names as Liebig, Perkin, Hoffmann, Verquin, Graebe and Liebermann, Caro, Peter Griess, Martius, Walter, Baeyer, Sand-Meyer and Heumann.

The history of the scientific pharmaceutical industry commences in this book with the founding of the first institute for experimental pharmacology by Buckheim in Estonia in 1849. Then follows the bacteriological and antiseptic discoveries of Semmelweis, Pasteur, Lemaire, Lister and, last but not least, Socin in Basle, who in 1871 was using phenol for wounds. Then on to Robert Koch's *in vitro* cultivation of bacteria and the work of Ehrlich on the application of dyes and arsenicals to medicine. Among the newer bactericides we read how Prontosil (Domagk 1935) led to 'Cibazol' (Ciba—1938, better known to us as Sulphathiazole). In 1950 the La Roche group produced Isoniazide (for tuberculosis) and Ciba in 1958 introduced 'Ciba 1906' for leprosy.

Turning to drugs derived from natural precursors we are told the story of Nupercaine (Ciba 1929), Dolantin (1940) and Cliradon (Ciba 1949) and of Butazolidine (Geigy). (The latter derived from quinine in the mistaken belief that antipyrine is a quinoline derivative.)

Similar treatment is given for very many other organic medicaments: Ergotamine (Sandoz 1918), Coramine (Hartmann of Ciba, 1918), Priscol and Privine (Ciba 1939), and the isolation of Reserpine in 1952 (Ciba). Vitamin C was first synthesized by Reichstein in 1933 and within two years La Roche were manufacturing it. In the 'thirties Ciba helped to isolate progesterone and later worked with Reichstein on cortisone.

Part 2 finishes with a historical account of plastics, from ancient ceramic arts via gun-cotton (Schoenbein of the University of Basle in 1845), celluloid, the Chardonnet denitrification process, to the important modern epoxy resins of to-day such as Ciba's 'Araldite'.

The plain grey board covers of this book give no hint of the wealth of material within. Beautifully printed on high-quality paper with hundreds of illustrations, dozens of which are in beautiful colours, it stands in a class of its own.

I have noticed only one error of fact (p. 123). The dibromoanthraquinone which Graebe and Liebermann hydrolysed to alizarin was, in fact, the 2 : 3 dibromo compound and not the 1 : 2 as described, although this piece of 'research luck' was not discovered until several years after the event. A few expressions strike the English reader as unusual, for example, "in six years the price of quinine *dove* from 1·3 to 2·5 florins per oz.", "diazo dyestuffs" (we say 'azo dyes'), and the use of the word 'somnifacients' for what we (with perhaps less Latin and more Greek) call 'hypnotics'.

This work reflects great credit on Drs. Huber and Menzi, who wrote the text, on Drs. Wilhelm and Kappeli, who had the idea of thus celebrating Ciba's seventy-fifth anniversary, on the photographers and blockmakers, and on all those concerned with the book. All who are able to obtain a copy are indeed to be envied.

L. K. SHARP

QUANTUM CHEMISTRY

Quantum Chemistry

Methods and Applications. By R. Daudel, R. Lefebvre and C. Moser. Pp. xiii+572. (New York: Interscience Publishers, Inc.; London: Interscience Publishers, Ltd., 1959.) 14.50 dollars.

It is an interesting exercise to speculate on the probable contents of a new book on quantum chemistry. One can be fairly sure that there will be a discussion of the particle in the box, the hydrogen atom, the hydrogen molecule-ion, the hydrogen molecule itself and possibly methane, ethylene and benzene. But for the serious student of the subject it is the rest of the contents which will excite his main interest. The books entitled "Quantum Chemistry" which are already on the market differ very greatly in what their authors have seen fit to add to this rather pedestrian list of topics. The book by Eyring, Walter and Kimball makes much use of the theory of groups in the interpretation of spectra and is one of the best elementary sources for information about electromagnetic phenomena; on the other hand, in that book there is almost no discussion of the diverse and sophisticated facts of chemical reactivity. The book by Pitzer covers widely the basic principles of chemical physics, and lays considerable stress on statistical mechanics and molecular dynamics. Here again, however, there is virtually no discussion of chemical reactions in terms of molecular structure. The big book by Kauzmann is very largely devoted to atoms and the author never really crosses the border from physics into chemistry. Clearly, the word 'chemistry' means something quite different to these authors from what it means to the vast majority of chemists.

Now we have yet another book with the same title and a much braver effort. This new book, by Daudel, Lefebvre and Moser, represents a creditable attempt to set down in an orderly manner those developments which in recent years have made quantum chemistry a subject of real interest to the experimental worker. The centre of gravity of the book is the unsaturated hydrocarbons and their physical and chemical properties. This is not inappropriate, since until quite recently it would have been true to say that this particular field of study had yielded a greater crop of quantitative results than any other branch of theoretical chemistry. It is inevitable that a book of this sort should dwell on certain topics at the expense of others, and it would be easy to criticize the authors for having omitted any discussion of the recent striking advances in, for example, the theoretical chemistry of the transition elements. But this would be ungrateful, as the authors have obviously taken pains to include reference to the most important papers in the theory of conjugated molecules; the fact that their book is not as broad as its title suggests only bears witness to the great rate at which theoretical chemistry is now developing.

Turning to details, one is glad to have a clear account of the theory of antisymmetrized wave functions and the Hartree-Fock equations. Of less value is the short chapter on biochemical applications: we still know so little about the cell that it seems premature to attach any weight to a quantum mechanical theory of carcinogenesis. Again, the order of the chapters is perhaps a little odd; the two parts of the book are linked together by only a very tenuous thread, and it is strange to have a chapter on reaction-rates preceding one on chemical equilibria. Perhaps also in the second edition the authors might consider whether, for example, their long tables of bond angles are worthy of the space which they occupy in view of the very cursory discussion which is given to this set of data. But it is a fault on the right side to make too much reference to experimental results; it would indeed have helped the reader to appreciate the strength of the more sophisticated theory if more comparisons had been given between calculated and observed excitation energies in conjugated molecules.

Taken all in all, this book is certainly a useful addition to the literature.

H. C. LONGUET-HIGGINS

HIGH-PRESSURE TECHNOLOGY

The Design and Construction of High Pressure Chemical Plant

By Harold Tongue. Second edition, revised. Pp. xii+250. (London: Chapman and Hall, Ltd., 1959.) 84*s*. net.

Since the first edition of this book was published in 1934 there has been a widespread increase in the use of high pressures in the chemical industry, particularly in the field of petrochemicals. New processes such as the polymerization of ethylene and the synthesis of diamond have been developed which operate at pressures and temperatures far greater than those attainable twenty-five years ago; furthermore, the advent of nuclear power has necessitated a great increase in the size of pressure plant. In order to describe the many developments in high-pressure technology that have made this progress possible, the text has been added to and modified considerably, so that this edition may be regarded as a new book on the subject.

The chief aim of the author was to provide a practical guide to the design of industrial high-pressure plant; although the work is mainly concerned with equipment used in the chemical industry, the general background of high-pressure technology is broadened by frequent references to the techniques used in the design of nuclear power plant. The practical nature of the book is emphasized by the inclusion of an introductory chapter devoted to the various codes of practice, specifications and statutory requirements for the design and operation of pressure plant. It is unfortunate that the references to British Standard 1500 on "fusion welded pressure vessels for the chemical and allied industries" which occur throughout the book concern the provisional code issued in 1949 and not the extensively revised edition published in 1958.

Although the pressure vessel codes give detailed practical design procedures for vessels operating at pressures up to about 200 atmospheres, for higher pressures there are as yet no accepted codes and the chemical engineer must base his designs largely on first principles. It is with the principles governing the design, fabrication and choice of material of construction for highly stressed vessels that the first half of the book is concerned. The basic theory underlying the design of both monobloc and compound cylinders is supplemented by the detailed results of recent experimental work on the yield and rupture of thick-walled cylinders. In addition to the well-known methods of fabrication, such as hollow forging and fusion welding, the newer techniques of tape-winding and the multi-layer form of construction are described in detail. In view of the increasing use now being made of the autofrettage procedure for extending the elastic range and prolonging the fatigue life of thick-walled hollow cylinders, the chapter dealing with this subject is disappointing in that very little design information is given. The same criticism may also be made of the section concerned with the problems of creep at high temperatures; furthermore, no mention is made of the effect of fatigue on design. On the other hand, much useful information, not readily accessible in the literature, has been brought together in those sections of the book which deal with the low-temperature embrittlement of steels and with those corrosion problems peculiar to high-pressure plant.

The second part of the book, which is mainly concerned with ancillary equipment such as pumps, compressors and valves, provides the reader with well-illustrated and detailed descriptions of a large number of designs. Since the requirements of industrial processes are so diverse, the author has had to exercise careful judgment in selecting suitable examples to demonstrate the salient features of the various items of plant. In addition, much useful information is given concerning the techniques employed in a number of continuous high-pressure catalytic processes and the methods used for the preparation and purification of industrial gases.

Unhappily the author died earlier this year, soon after the publication of this edition of his first book. In compiling it, he has performed a valuable service to all those interested in the field of high-pressure technology. K. E. BETT

ANNUAL REVIEW OF ENTOMOLOGY

Annual Review of Entomology

Vol. 5. Edited by Edward A. Steinhaus and Ray F. Smith. Pp. vii+451. (Palo Alto, Calif.: Annual Reviews, Inc., 1960. Published in co-operation with the Entomological Society of America.) 7 dollars.

THE aim of this "Annual Review" is to cover the whole science of entomology, pure and applied; and since the insects provide at least five-sixths of all known species of animals, are exceedingly diverse in form and function, have a tremendous influence on the economy and health of man, and are being studied by a very large army of investigators—there is no shortage of material for annual review. The study of some subjects has only recently begun. It is still possible for all work on the fine structure of insects to be summarized in a single article (G. A. Edwards). Cytogenetics of insects has been studied for many years and the review by S. G. Smith covers only selected highlights from the recent literature. A few years, ago a review dealing with the biochemistry or neurophysiology of insects would have been a rather unsophisticated affair, from sheer lack of knowledge. But that is no longer so; the article on insect flight muscles and their physiology (E. G. Boettiger) shows that in both these fields new basic ideas are being worked out on insects. In the physiology of neurosecretion, which is well reviewed by W. G. Van de Kloot the insects have always led the way.

The editors of the "Annual Reviews" maintain a constant effort to persuade their authors to present a point of view and not just an annotated catalogue of references. They score a fair proportion of successes with their entomologists. In writing on host selection in phytophagous insects A. J. Thorsteinson contests the assumption made in an earlier review by Fraenkel and Lippe that only the adventitious flavours of plants are utilized in host selection, never the nutrients themselves. But if a point of view is put too strongly a review can degenerate into a polemic. In surveying once more the question of population control, H. G. Andrewartha and L. C. Birch make a serious effort to get away from the sterile theoretical arguments about density-dependent factors and to discuss some actual contributions to the study of insect abundance in Nature. Mechanisms of resistance are again reviewed, this time by A. W. A. Brown, who quotes 229 references; a number exceeded only by L. R. Jeppson and G. E. Parman, writing on insects and mites as pests of citrus, who have 240. That represents about half of the twenty articles in this volume. The range of subjects covered is so wide that every year there is plenty of material to choose from which really needs reviewing. The high standard of earlier volumes is maintained this year.

The print in these volumes is rather small, which reduces the impact of their content on the reader; but it is pleasant not to have them printed on the highly sized paper so much favoured in the United States. However, a substantial number of pages in the copy received for review showed the letterpress on the other side of the page so clearly as to be difficult to read. V. B. WIGGLESWORTH

THE LAND OF THE MARSUPIALS

Biogeography and Ecology in Australia
Edited by A. Keast, R. L. Crocker and C. S. Christian. (Monographiae Biologicae, Vol. 8.) Pp. iv+640+18 plates. (The Hague: Dr. W. Junk, 1959.) 65 guilders.

THE continent of Australia is about the same size as the United States or 25 times the area of the British Isles. Sydney was settled in 1788, but it was not until about 1825 that other coastal areas began to be developed. The 'gold rushes' brought a great increase of population in the mid-nineteenth century. It was not until a little more than a century ago that the dawn of scholarship came with the establishment of the Universities of Sydney and Melbourne.

In the pioneer era, the studies of the infant departments of biology were of necessity concerned largely with the description of local fauna and flora. In later years, however, the pendulum of interest swung remarkably so that the chief studies of a majority of senior academic zoologists were of problems that could be rather more efficiently attacked in London or New York. The wonder, then, is not that Australians know so little about the ecology, biogeography and physiology of their native fauna, but (as is shown by the present volume) that they know so much. It is significant that much of the new zoological knowledge is not due to the efforts of university workers, but to officers of the splendid Commonwealth Scientific and Industrial Research Organization.

"Biogeography and Ecology in Australia" will be valuable not only for ecologists but also as a general reference book for university teachers, senior students and biologists in general. (For example, how many know that there are only 11 fewer eutherians than marsupials in "the land of marsupials"?) The book brings together much of the available knowledge, as well as enabling us to see where the gaps are. The first essay deals with "The Uniqueness of Australia in Biology" (by F. S. Bodenheimer) and then follow thirty-six chapters on the ecology of primitive aboriginal man, contemporary human ecology, that of the vegetation, the extant chordate classes, some of the major invertebrate groups and other topics. Pleasing evidence that, largely under the impetus of a Swiss and an Englishman, Australians are at last beginning to study the biology of Australian mammals is found in the chapters by Main *et al.* and Sharman. Among the hitherto unsuspected physiological adaptations of certain pouched mammals is rumination. Delayed implantation, too, has been demonstrated in two species by Sharman and Ealey and others within the past few years. A. J. MARSHALL

CLIMATIC ATLAS OF THE CZECHOSLOVAK REPUBLIC

Atlas Podnebí Ceskoslovenské Republiky
Pp. 42+100 plates. (Praha: Ústřední Správa Geodesie a Kartografie, 1958.) Cena Kčs. 300.

THIS impressive book contains 89 charts of Czechoslovakia on the scale of 1 : 10^6 and eleven diagrams. The maps, which measure about 2 ft. 6 in. by 1 ft. 6 in., are beautifully printed in attractive systems of different colours for areas of different values of the elements concerned. East and West Germany are the only other countries to have produced a climatic atlas with maps of so large a scale.

Detailed descriptions of the contents are given in English, Russian, and French as well as Czech.

The first nine charts give the administrative areas, river basins, soil types, forest regions and climatic regions based on Končck's humidity index for the vegetation period.

Next there are thirty-one temperature charts which give mean monthly and annual isotherms of screen temperature (that is, not reduced to mean sea-level), mean numbers of days of maximum temperature over 25° C., of maximum below $-0 \cdot 1°$ C., etc., mean first and last frost days, and the mean duration of various periods such as the one of mean daily temperature 5° C. or more. The mean temperature of the day is defined as $(7)+(14)+2(21)/_4$, (7), denoting the temperature at seven hours, etc. In summer this probably gives a rather higher value than the customary British formula of average of maximum and minimum. As charts of mean values they are excellent, but for an area of such variable weather as Central Europe they much need to be supplemented by information on extremes. Extremes are not mentioned anywhere, yet other sources give the following table for Prague in January:

VALUES IN °F.

Average daily		Average highest in month	Average lowest in month	Absolute max.	Absolute min.
max.	min.				
34	25	45	8	55	−16

The information outlined on average monthly extremes and absolute extremes is the least information on variability which ought to be included for scientific and economic purposes.

The section on precipitation contains mean monthly and annual amounts, means for the vegetation and winter periods and the mean numbers of days with precipitation exceeding 1 and 10 mm., days of snowfall and snow cover, etc. Next there is a section with maps of wind-roses, averages of relative humidity in July and December, mean cloudiness in September, November and the year, annual numbers of days of fog, sunshine, and thunderstorms. These are standard features of most climatic atlases, but for a country of mixed terrain like this much is lost by giving only annual values of sunshine since it is well known that there is a marked seasonal difference between the relative sunshine distribution in mountains and plains.

Finally, there are twelve phenological charts (mean date of apple-blossoming, harvesting oats, etc.) and eleven charts of seasonal variations of soil temperature. The latter, with examples for a hot summer and a severe winter, are the only sections of the book to give any indication of extreme values.

The period of the observations used is mainly 1901–1950 but is 1926–1950 for some and 1946–1953 for wind-roses. The preface mentions that it is intended to publish a volume of tables but suggests that this will contain only the data used in drawing the isopleths of the work under review. It is much to be hoped that the tables will in fact contain some data on extremes of temperature and precipitation if it is not possible to go all the way and provide an airmass climatology similar to that published in 1958 for West Germany (*Ber. deutschen Wetterdienstes* No. 45. "Zur Klimatologie der Grosswetterlagen", by K. Bürger.) G. A. BULL

Physics and Chemistry of the Earth

Vol. 3. Edited by Prof. L. H. Ahrens, Frank Press, Kalervo Rankama and S. K. Runcorn. (Progress Series.) Pp. viii+464. (London and New York: Pergamon Press, 1959.) 100*s*. net; 15 dollars.

THIS volume contains admirably concise chapters by J. W. Durham on palæoclimates, by A. G. W. Cameron on the origin of the elements and by D. C. Tozer on the electrical properties of the Earth's interior. S. I. Tomkeieff, in "Geochemistry in the U.S.S.R. (1954–1956)" gives a partially annotated bibliography of about 1,200 titles which is an extremely useful list of Russian publications dealing with igneous, metamorphic and sedimentary rocks, geochemistry, cosmochemistry, mineralogy and natural waters. It is a sad reflexion on the state of scientific libraries in Britain that some of these publications are unobtainable anywhere in this country. The geochemistry of thorium and uranium is reviewed by J. A. S. Adams *et al.*, while in "Silicate Melt Systems" E. Roedder reproduces about sixty phase-diagrams dealing with various portions of the geologically important system K_2O—Na_2O—CaO—FeO—MgO—Fe_2O_3—Al_2O_3—SiO_2, and he gives a helpful summary of the experimental techniques used. Unfortunately there is no attempt to relate the diagrams to petrology in the way pioneered by N. Bowen more than thirty years ago.

Nearly half the book deals with geophysical investigations in the eastern Caribbean by C. B. Officer *et al.* and the continental margin of the east coast of North America, north of Cape Hatteras, by C. L. Drake *et al.* Much undigested detail quite unsuitable for a general review is contained in both these articles, and this has probably been the chief cause of the increased price (100*s*.) compared with either Vol. 1 (70*s*.) or Vol. 2 (63*s*). For example, the former article contains no less than 55 pages of seismic profiles and their interpretation while the latter contains 13 pages on 'significant' boreholes in eastern America and the important basement rocks encountered ('decomposed rock'; 'bedrock'; 'crystalline rock'), various figures and text, all of which fail to give the reader a picture of the basement.

B. E. LEAKE

The Measurement of Grassland Productivity

Proceedings of the University of Nottingham Sixth Easter School in Agricultural Science, 1959. Edited by Prof. J. D. Ivins. Pp. viii+217. (London: Butterworths Scientific Publications; New York: Academic Press, Inc., 1959.) 35*s*.; 7 dollars.

FOR several years the University of Nottingham has organized an Easter School in a branch of agricultural science. At the 1959 School, on measuring grassland productivity, 20 papers were given, which are published in this book, together with summaries of the discussions.

Grass occupies two-thirds of British farmland, but current production from it is much less than would be possible if existing knowledge of improved varieties, fertilizers and techniques of management were fully applied. Lack of confidence in methods for measuring grassland productivity hinders these developments and this School was organized to review and discuss current methods.

In the opening session Dr. William Davies reviewed the history of methods of measuring grassland output; corresponding German work during the past twenty years was described by Prof. E. Klapp. T. E. Williams then gave a good account of the effect of leys on the productivity of arable crops grown after the leys were ploughed.

A second group of papers dealt with the growth characteristics of different herbage crops and the problems of assessing their relative merits. Herbage has no true value until it has been used by an animal, so the third group of three papers discussed methods of assessing how much grass is actually eaten by stock in grazing experiments. Eight papers dealt with assessments of animal production from grass, and with correlating estimates of pasture growth with the performance of animals using the herbage. Three of these papers discussed the digestibility of herbage in pasture experiments.

Two papers described farm-scale measurements. Work done by Imperial Chemical Industries, Ltd., on commercial farms showed that measurements of grassland production must be related to output from the whole farm business; single measurements of productivity, and particularly physical measurements, can be misleading. Mr. Rex Patterson showed how his farm records of grazing have been used to measure pasture productivity and also quality.

The papers cover the subject well although their quality varies; together they provide a good review and the book is recommended to those concerned with scientific work on grass.

G. W. COOKE

Handbook of Toxicology

Vol. 3: Insecticides: a Compendium. By William O. Negherbon. Prepared under the Direction of the Committee on the Handbook of Biological Data, Division of Biology and Agriculture, National Academy of Sciences—National Research Council. Pp. xxv+854. (Philadelphia and London: W. B. Saunders Company, 1959.) 98*s*. net.

THE insecticides volume of the "Handbook of Toxicology" is an impressive production which is well calculated to save an immense amount of time for anyone seeking the available information about the great range of chemicals that are in use as insecticides and synergists at the present time. The contents are arranged alphabetically under the preferred chemical names of the substances. But interspersed among these are general articles on such subjects as anti-metabolites, bees and insecticides, cytochrome oxidase (effect of insecticides on), resistance, temperature and insecticidal action and others. Some of these sections help to lighten the subject-matter, as do the introductory sections dealing with each insecticide or group of insecticides. Under a given substance will be found an account of its chemistry; toxicity for man and wild-life; toxicity for insects; factors influencing toxicity; entry and mode of action in the insect; formulations; resistance; all these subjects being illustrated by exhaustive compilations of tabulated data. An insecticide such as DDT on which a vast literature exists will have about 40 pages devoted to it. Original references are quoted for every piece of information; the reference list contains 3,404 titles. There are separate indexes to chemical compounds, and to the scientific and common names of insects.

This should prove a most valuable work of reference. The short general introductions to the various sections can be read with interest by anyone looking for a broad survey of the subject.

V. B. WIGGLESWORTH

NUCLEAR TRAINING FACILITIES AT THE ROYAL NAVAL COLLEGE, GREENWICH

By Prof. J. EDWARDS

THE Royal Navy, with one nuclear submarine, *Dreadnought*, well under construction, and another likely to follow, with a land-based prototype plant at Dounreay also well advanced, and a possible interest in nuclear surface ships, has an obvious need to ensure a continued output of officers fully trained in the theory, techniques and problems of nuclear propulsion systems to meet its specific requirements. To provide this, the Department of Nuclear Science and Technology was set up under me at the Royal Naval College at Greenwich in January 1959.

The responsibilities of this Department were to provide courses suitable for those officers responsible for the operation of the nuclear submarines and for the prototype at Dounreay, and also to provide an advanced course suitable for those technical officers and civilians who would go to the Design Departments of the Admiralty concerned with nuclear propulsion. At present all reactors under construction for these purposes are of the pressurized-water type, and the courses are therefore aimed at this system in particular and the small mobile reactor system in general rather than the large gas-cooled graphite-moderated reactors used in the land-based power station programme.

The course for the submarine officers and operators lasts six months and that for the designers one year; both are of high academic standard demanding good mathematical knowledge, and cover atomic and nuclear physics, chemistry and metallurgy, reactor physics and kinetics, shielding and heat transfer, servo-mechanisms and control systems, and detailed information on the actual plant systems and components to be installed in the submarines. In the case of submarine officers of H.M.S. *Dreadnought*, they, on successfully completing the course, proceed to the United States to undergo a period of practical training in sea-going nuclear submarines of the United States Navy. This facility will later be replaced by training on Great Britain's own prototype at Dounreay when this is commissioned. Those officers and civilians who successfully complete the six-months course and who stay on for the advanced course spend a further term in which the main emphasis is given to a detailed design study of a mobile reactor system, to additional experimental work, and to a series of lectures from experts from the Atomic Energy Authority and industry related to safety aspects, metallurgical topics including radiation damage and fuel element fabrication, steam generator design and steam cycles, radiochemistry, advanced mobile reactor systems, and more detailed reactor physics and core design studies, relating to flux flattening, burn-up, control problems and the use of burnable poisons, etc. The design studies, although at first concentrating on the pressurized-water systems, will gradually be extended to cover other systems of interest to marine propulsion, namely, boiling-water reactors, organic moderated reactors, high-temperature gas-cooled reactor systems and others. These lectures are supplemented by additional visits to centres of nuclear research, fabrication and construction.

The six months reactor course is necessarily predominantly theoretical but nearly a dozen basic physics experiments have been introduced to give the students familiarity with the detection and measurement of radiation, and basic health and safety precautions and monitoring instruments. These cover the normal Geiger counter experiments, the measurement of half-value thickness of various materials, calibration of scintillation spectrometers, measurement of beta absorption curves, and the back-scattering of beta particles. Some neutron transmission experiments have also been introduced in which neutron cross-sections, as well as diffusion and slowing-down lengths of neutrons, are measured. The neutrons for these experiments are provided by a neutron 'howitzer', essentially a carefully designed storage shield for a polonium–beryllium neutron source of about 1 c. The neutron howitzer consists basically of a steel drum containing a 10-in. thickness of paraffin surrounding the source. A number of vertical and horizontal ports or beam holes are provided for the experiments together with means for accurately positioning the source and the experimental equipment.

An important facility from the point of view of the reactor operators is the reactor simulator. This has been built by Vickers-Armstrongs (Aircraft) Ltd., and is largely based on their *Mk. II* design modified in certain aspects to meet the specific requirements of the Department. These machines are based on analogue computer principles, and by means of electronic circuits the equations relating to neutron flux, reactivity and time in a nuclear reactor are continuously solved. Various configurations of fuel and moderator with an associated range of prompt neutron life-times can be represented, and studies of the effectiveness of automatic control systems and the changes of reactivity due to fission product poisoning, temperature coefficient and thermal transient effects can be carried out. The control panel instrumentation provides most of the important indications given on the control desk of a full-sized reactor, including pen recording on logarithmic and linear power scales, a logarithmic power-level meter, and a doubling time or period meter. Automatic start-up is provided, as well as a 'demand-power' function generator with meter display. A temperature effect is also built in, using a temperature proportional to power, with a suitable time-lag, a temperature trip and a meter display of average coolant temperature. Safety simulation is obtained by the incorporation of various safety trips and interlocks to provide actual reactor safety trip responses. A large range of experiments can be undertaken with the aid of this machine, and include reactor start-up procedure, approach to maximum power-level, step changes in reactivity, doubling time and reactivity variations,

poisoning effects and simulation of 'accident conditions'. It therefore provides a comparatively inexpensive training device very suitable for experiments following on the theoretical teaching on reactor kinetics and control, and prior to actual power reactor operational training.

It is planned also to install shortly a sub-critical reactor in the Department (Fig. 1). This is being built by Miles-Hivolt and is largely based on a design evolved in the University of Birmingham, suitably modified to the Royal Naval College requirements to provide additional flexibility in the experiments to be carried out with this equipment. The facility is a light-water moderated, natural uranium assembly, using a small but powerful accelerator to produce neutrons. The latter can be used either as a continuous or pulsed source of mono-energetic neutrons, free of the γ-radiations emitted by most radioactive sources. It is easily transportable and can therefore be used independently for a variety of other nuclear physics experiments. The five tonnes of natural uranium rods are in the form of as-cast uranium rods canned in aluminium, 43½ in. long by 1·22 in. diameter. These are supported in two vertical lattice plates to form a horizontal array on a square pitch of 1·9 in. to an accuracy of better than 0·005 in. The assembly is supported in a space frame at a variable height and contained within one of two stainless steel moderator tanks which can be winched into position and provide either an unreflected system with one tank, or some 6 in. of water reflector with the other tank. A dump tank, pump, and water treatment plant are also provided. A platform around the structure provides easy access for the assembly and positioning of monitoring and counting equipment, and a special traversing mechanism is supplied to enable accurate positioning of such equipment in three dimensions to be carried out. A source tube 1 in. in diameter passes horizontally through the system and is coupled to the 150-kV. ion accelerator. The deuterium or tritium target for neutron production can be placed at any position in the tube, which in turn can be placed in any one of four alternative positions through the lattice. The accelerator, which requires a power supply of about 8 kV.amp. and a cooling water supply of 5 gallons per min., is capable of giving a maximum beam current between 0·75 and 1·00 m.amp. either with hydrogen or deuterium ions and can be operated continuously, or with a pulse repetition rate between 0·65 and 3 kc./sec. giving a neutron output between 10^9 and 10^{10} neutrons per sec. of either 3 or 14 MeV. energy, depending on the beam and type of target used. The advantages of using an accelerator as a neutron source instead of a powerful radioactive source are that one no longer needs extreme care in the shielding, handling and transport of the source; one can literally turn the neutrons on and off at the turn of a switch, and no expensive and time-wasting re-irradiation of the source is required. Some of the experiments which will be carried out to give the students an understanding of reactor core phenomena and essential design parameters include measurement of buckling, multiplication factor, thermal utilization factor, criticality measurements, neutron migration lengths, prompt neutron reactivity, time constants of the assembly and neutron lifetime studies for prompt and delayed neutrons. The equipment, however, due primarily to the pulsed neutron facility, will also provide adequate opportunities for research to be undertaken by the staff of the Department.

Other experimental rigs now being designed include two heat-transfer loops, for gas and liquid heat-transfer studies, and a large-scale shielding experiment to be used in conjunction with the accelerator. To provide some additional experience with an actual critical facility short training visits are being arranged with Hawker-Siddeley's Nuclear Power Co. at Slough, to enable students to become acquainted with operational procedures and experimental uses of the firm's 10-kW. Jason reactor. It is hoped to obtain a more advanced computer than the reactor simulator mentioned above.

The first full reactor course of six months has now just been completed, and a second six-month course is about half-way through its final term, as is the first advanced course. Results have been most encouraging, and it is evident that a firm foundation for training in nuclear propulsion systems has now been established. Additional and more general courses in nuclear science and technology lasting two weeks and six weeks respectively are to be instituted in the near future to cater for those concerned with other and broader aspects of nuclear propulsion.

The Department is situated in one of the historic and beautiful buildings designed by Wren of the Royal Naval College, and although this posed some problems in its internal conversion to nuclear laboratories, the building has been adapted surprisingly well. Two laboratories are provided, one on the third floor and one on the ground floor, each with its associated offices and instrumentation test facilities. That on the third floor, which is in close proximity to the main offices, lecture rooms, stores and electronic workshop of the Department, is used for the basic nuclear physics experiments involving, in the main, sources of only low activity, generally less than 1 mc. Facilities are also provided here for preparation of specific sources from radioactive liquids. The other laboratory is designed to provide storage and handling space for sources of several curies of activity as well as facilities for the storage of any accumulated solid and liquid active waste. This laboratory will house the larger and heavier experimental equipment such as the sub-critical reactor, heat-transfer loops and the large-scale shielding experiments referred to above. Consideration has also been given to the possibility of ultimately housing a low-power research and training reactor. Clean room, offices and adequate crane lifting capacity have been provided together with a dark room for the processing of film used in some experiments and for instruction in radiographic techniques. The conversion of this laboratory is now practically complete and the installation and commissioning of the sub-critical facility in which the advance course students will participate will begin towards the end of September.

Fig. 1 is a drawing of the sub-critical facility.

HUMAN AND OTHER ANIMAL CELLULOSE

By Dr. D. A. HALL and H. SAXL*

Department of Medicine, University of Leeds

PRIOR to the observations[1,2] that anisotropic fibres consisting partly of cellulose and partly of protein, exist as a minor but normal constituent of mammalian tissue, the only form of cellulose which could unequivocally be ascribed to the animal kingdom occurred in the tests of the tunicates. Evidence has also been advanced for the presence of cellulose in the outer layers of silk fibres from *Bombyx mori*[3], and other species of silkworm, but there is no evidence that this material is in any way oriented, nor is its identity proved beyond doubt[4].

We have therefore investigated the origin and comparative relationships of the cellulose-containing fibres of mammalian tissue. To do this, five different tissues have been examined, all rich in neutral polysaccharide, but differing markedly in site and function. These were: cotton fibres as representative of plant cellulose, anisotropic fibres from an affected area of the dermis of a case of scleredema adultorum of Buschke[5], a preparation from aged human aortic media, finely dispersed material from the basement membrane of pig kidney and the mid-portion of the test of the tunicate, *Ascidiella aspersa*.

Polarization and Electron Diffraction Observations

Polarization and electron diffraction results were correlated. It has been observed previously[6,7] that tunicin is composed of layers of interwoven anisotropic fibrils, and in addition it contains anisotropic fibres or lamellæ similar in all respects to those of mammalian tissue. Frozen sections of human aortic tissue also show the presence of the mammalian type of anisotropic fibre resembling presumably the anisotropic structures reported by Hass[8] as early as 1943. Aortic tissue preparations were also obtained by the fractionation of the pooled media of aged human aortas (50–70 years old) after removal of the collagen by exhaustive extraction with boiling dilute acetic acid[9]. Fractionation with boiling 40 per cent urea

---

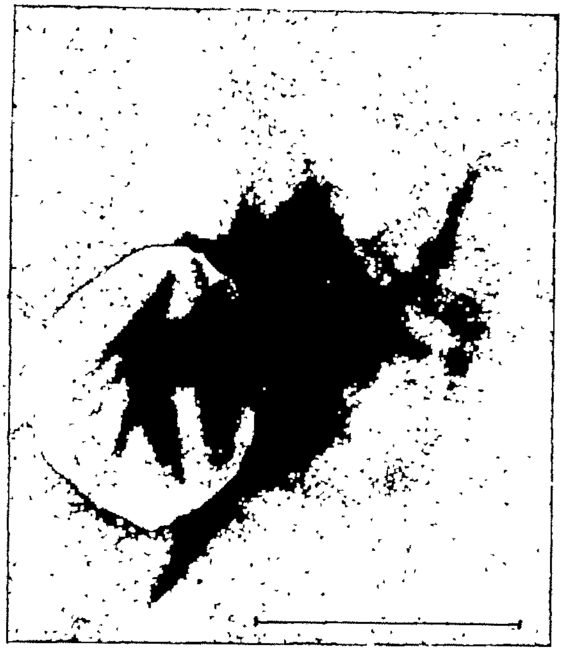

Fig. 1. Reticulin from the basement membrane of the kidney of a pig, exhibiting a laminated structure (ref. 11); isolated by cutting thick frozen sections (about 200μ) of the unfixed cortex from a region about 0·4 mm. internal to the capsule, followed by ultrasonic dispersion (for about 2 min. at 14,000 r.p.s.) (kidney obtained from freshly killed animals). The light area is that from which the electron diffraction pattern, demonstrated in Fig. 2, was obtained (the method has been reported in ref. 2) (× 24,000)

solution gave, after dialysis and filtration, a solution of pseudoelastin[10] which also contained small anisotropic particles (0·05–0·1 mm. in diameter). Particles of about similar size and having the same optical properties were observed in suspensions containing reticulin from basement membranes of pig kidney obtained by ultrasonic dispersion (Figs. 1 and 2); although reticulin in its native state is normally regarded as isotropic[11], it would appear possible that the ultrasonic dispersion has revealed some material which has a marked degree of anisotropy. Dermis from the lesion of Buschke's scleredema contained large numbers of anisotropic fibres of mammalian type.

Although X-ray diffraction studies give a fibre diagram for plant cellulose, this was not observed with electron diffraction studies[2], since the small number of micelles gave a Debye-Scherrer diagram, which is characteristic of amorphous or polycrystalline material. A fibre diagram was, however, observed for scleredema and tunicate cellulose with electron diffraction methods, indicating a greater degree of orientation at this level of organization. Classification was, however, also possible on the basis of the relative intensities of the reflexions. Electron diffraction patterns of the aortic pseudoelastin[10] and renal reticulin preparations included reflexions which were indistinguishable from those of cellulose as exemplified by fibres from human dermal tissue, cotton or tunicin. The intensities of the various reflexions differed considerably however. The heights of the peaks in the densitometer tracings are recorded in arbitrary units chosen to suit each plate. No direct comparison can therefore be made between the absolute values in different tracings. Relative values are, however, comparable. The main observation which can be made from the two sets of curves (Figs. 3 and 4) is that the manifestly fibrous forms (plant cellulose and that from human pathological dermis) are characterized by reflexions of considerable intensity from the 021 and 002 layers. Haphazardly oriented material, on the other hand, shows a more general spread of intensities over a number of different reflexions. Tunicin, although fibrillar, demonstrates a diffraction pattern similar in many respects to that of pseudoelastin and reticulin, and it is thought possible that this similarity may be related to the presence of a layered structure. However, the diffraction pattern of tunicin is characterized by the fact that the reflexions form arcs, indicating the type of orientation which Mark and Susich[12] ascribed to layers aligned at a constant angle. Similar arcs were observed in patterns from the fibres of scleroderma tissue, where cellulose sheets surround the protein template in layers.

Not only can the various polysaccharides be identified as having similar electron optical properties by the positions of the various reflexions, but also the human fibrous form can be shown to react in exactly the same fashion as the plant material to partial hydrolysis with hydrochloric acid[13], which is accompanied by changes in the crystal structure characterized by alterations in the diffraction pattern. The most obvious change under the conditions employed here is an intensification of the third-order reflexion from the 021 layer relative to the adjacent reflexion from the 002 layer. As can be seen from Fig. 3, this change occurs equally in both human and plant cellulose.

Biochemical, Histochemical and Electron Microscope Observations

These observations were made on the reticulin and the pseudoelastin fraction from aorta. Following intradermal injection of pectinase[14] into a guinea pig, microdissection of the reticulin layer of the dermal epidermal junction can be observed, and polysaccharide from this region is liberated into the tissue to form a broad band with positive periodic

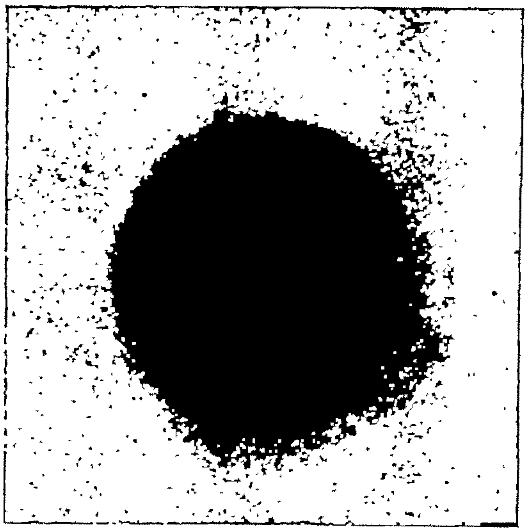

Fig. 2. Electron diffraction pattern from the area indicated in Fig. 1. The two most intense rings correspond to reflexions from the 101 and 021 layer lines of cellulose. The net plane indices of the other reflexions are indicated in the densitometer tracing in the upper section of Fig. 4. The broad diffuse band underlying the 021 ring represents the reflexion corresponding to the 2·86 Å. spacing of the haphazardly oriented array of collagen fibrils in the reticulin. Photographs taken with Elmiskop I

acid–Schiff reaction[13]. These observations could be related to the examination of bullous lesions of human dermis. *In vitro* studies demonstrated that the amount of polysaccharide liberated, following pectinase action, is much greater from sclerodermatous than from normal tissue. Electron microscope examination of the pathological dermis revealed how the formation of cellulose fibres from this polysaccharide might occur. It was suggested earlier[3] that the initial stage in the formation of anisotropic cellulose fibres in mammalian tissue may necessitate the presence of a protein template and that this might well consist of partially degraded collagen. In the case of reticulin, it appears that the template may in fact consist of a network of intact collagen fibrils. In pathological dermis, different stages in the transformation from reticulin-like fibrils to highly crystalline ones were observed. Cellulose micelles are preferentially adsorbed on to collagen in the regions of the a, b_1 and b_2 bands, thereby forming complexes which act as nuclei for the growth of cellulose crystallites.

High concentrations of neutral polysaccharide were also observed in the pseudoelastin preparations from arterial media. Total polysaccharide and uronic acid determinations made it possible to deduce that the neutral polysaccharide was firmly bound to a protein fraction, the so-called pseudoelastin which followed collagen but preceded elastin into solution in urea solution. This particular protein has the same amino-acid analysis as that reported for the protein fraction of anisotropic fibres in other tissues, and hydrolysis showed glucose to be the major sugar component. Not only was the solubility of old pseudoelastin (67 yr.) greater than that of a similar preparation from young tissue (20 yr.), but also the amount of cellulose-like neutral polysaccharide associated with it was increased. Apparently this was linked with an associated decrease in mucopolysaccharide content, since the total polysaccharide content was not greatly affected by age.

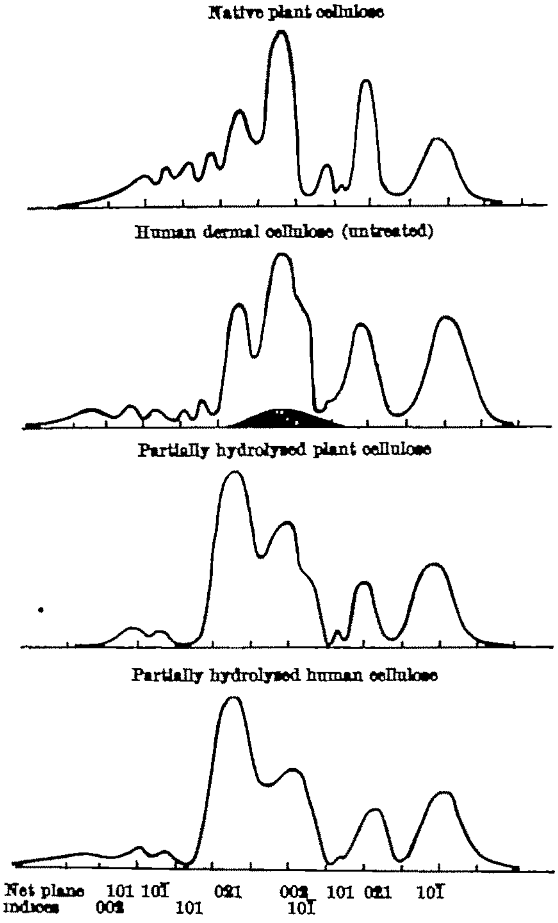

Fig. 3. Densitometer tracings of diffraction patterns from native plant and human cellulose (scleroderma dermis) and from similar material after partial hydrolysis following 5 hr. boiling under reflux with an azeotropic aqueous hydrochloric acid solution

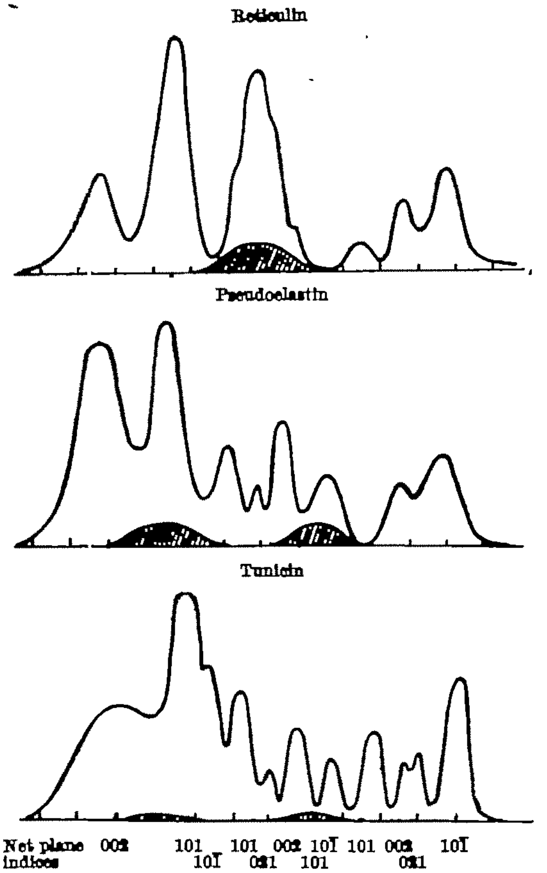

Fig. 4. Densitometer tracings of diffraction patterns from (*a*) pig kidney basement membrane (cf. Figs. 1 and 2), (*b*) a preparation (pseudoelastin) dissolved from human aortic media with boiling 40 per cent urea after the removal of collagen and ground substance with boiling 2 per cent acetic acid; and (*c*) a preparation of tunicin from the test of the tunicate *Ascidiella aspersa*. The shaded areas refer in (*a*) to the diffuse reflexions from the 2·86 Å. spacing in collagen, and in (*b*) and (*c*) to reflexions characteristic of the 2·0 and 4·4 Å. spacings of elastin

Frey Wyssling[14] has pointed out that interchain hydrogen bonds in the cellulose crystal lattice do not lie in the plane of the pyranose rings (the 002 plane) but in the diagonal 101, and to a less extent in 10Ī planes. The relative unimportance of the 002 spacing in preparations from reticulin, pseudoelastin and tunicin may therefore indicate that planar alignments of the cellulose chains are formed in these tissues, presumably due to the planar nature of the substrate on which they are deposited, as opposed to the three-dimensional crystal structure which results from deposition on a cylindrical template. Both reticulin and tunicin are known to be planar in arrangement, and it is to be expected that pseudoelastin, having been dried from solution, would crystallize in the simplest possible form. That such a simple structure is in fact in the form of a planar array has been demonstrated by Mukherjee, Sikorski and Woods[17] for mechanically or chemically dispersed plant cellulose microfibrils. It would appear therefore that, in the presence of a suitable substrate, hydrogen-bond formation in the 101 plane completely supersedes any interchain reactions in other planes, with the consequent formation of a layered cellulose structure. In all these cases, however, the presence of reflexions of low but finite intensity from the 002 plane must indicate that at least a portion of the polysaccharide has become associated with a template on which it is capable of forming a three-dimensional array and hence of producing a fibril. This deduction is in complete agreement with the observations of a limited number of anisotropic structures in these preparations.

The apparent similarity between the different protein polysaccharide complexes would appear to be of considerable significance. In all cases examined, the protein consists of either collagen or a degradation product of this, pseudoelastin. The nature of pseudoelastin has been discussed before[10]. The present work demonstrates that not only does pseudoelastin contain a basic amino-acid pattern but it also is a protein polysaccharide complex. Only in the case of tunicin and the mammalian dermal fibres has the polysaccharide been unequivocally identified as cellulose. The pseudoelastin fractions, by the nature of their method of preparation, cannot be identified as single compounds, but evidence from electron diffraction diagrams, examination in polarized light and chromatographic assessment of the sugar content of their acid hydrolysates would appear to indicate that the polysaccharide resembles cellulose, at least in so far as it consists in the main of β(D)-glucose molecules joined through 1 : 4 linkages. However, since similar anisotropic structures to those proved to contain cellulose can be observed in fibres containing chondroitin sulphate[3], it may not be necessary for all the linkages between the sugar residues to be 1 : 4.

That tunicates may represent the ancestors of the vertebrates has been discussed by several workers[18,19], and the similarity between the protein fractions to which mammalian and tunicate celluloses are attached may represent further evidence in support of this hypothesis. It does not appear inconceivable from the present observations that the polysaccharide–protein complex of reticulin may have been developed phylogenetically from the ancestral neutral polysaccharide–protein complex tunicin, on the pathway from tunicate to man, since only quantitative biochemical and biophysical changes would be required for such a development. Pontecorvo[20] has considered the possibility that evidence is available at a structural rather than a metabolic level for evolutionary development to be due either to changes in, or maintenance of, specific genetical characteristics. The appearance of increasing amounts of cellulose-like polysaccharide in combination with protein in ageing aortic tissue may indicate that similar genetical changes may occur during the ageing of an individual.

A fuller discussion of these results and their implications will be given elsewhere.

This work was mainly carried out while we were members of the Nuffield Gerontological Research Unit, University of Leeds. We thank Prof. R. E. Tunbridge, Dr. F. Happey and Prof. R. D. Preston for much critical discussion, and Prof. H. Magnus for the specimen of dermis from a case of scleroderma, and Dr. H. J. Woods for densitometer facilities.

COMPARISON OF FISSION PRODUCT AND BERYLLIUM-7 CONCENTRATIONS IN THE ATMOSPHERE

By W. ANDERSON, R. E. BENTLEY, R. P. PARKER, J. O. CROOKALL
and L. K. BURTON

Physics Department, Institute of Cancer Research, Royal Cancer Hospital, Fulham Road, London, S.W.3

SCINTILLATION spectrometry provides a convenient method of following the levels of specific γ-ray-emitting nuclides, and, since May 1959, we have been measuring the γ-activity of atmospheric dust collected from surface air by an electrostatic precipitator at Sutton, Surrey[1]. Apart from one sample which contained material from the first French nuclear test[2], we have been unable to measure the relatively short-lived zirconium-95 plus niobium-95 in samples collected after December 1959. We have therefore considered the principal γ-emitting fission products of longer half-life[3], shown in Table 1. The 0·51 MeV. γ-line of rhodium-106 was thought to be particularly suitable for following current trends in concentrations of fall-out materials in the air. However, difficulties are encountered due to the presence of other nuclides with similar γ-energies.

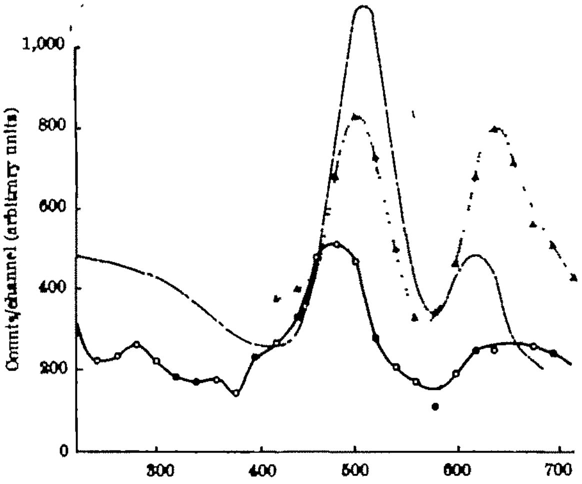

Fig. 1. Spectra of dust samples obtained with 3-in. crystal. - - -, May 1959; ——, December 1959; — — —, rhodium-106 reference standard

Fig. 1 shows the γ-spectra of two typical dust samples, one collected during May 1959 and the other during December 1959, measured with a 3 in. × 3 in. sodium iodide (thallium) crystal and 100-channel analyser. The spectrum of a rhodium-106 reference standard is also shown and it is found that the position of the principal peak in the spectrum of the May sample differs by not more than half a channel width from that of the standard. One channel width of our spectrometer corresponds to an energy difference of 0·020 MeV. In samples collected after December 1959 small but significant changes in the position of this photopeak were observed. Thus the position of the principal peak in the spectrum of the December sample is about 1·5 channels width from that of the standard, indicating an energy about 0·03 MeV. lower than the accepted value of 0·51 MeV. for rhodium-106[4]. This peak decayed initially with a half-life of about 70 days.

Detailed Analysis of 0·5 MeV. Peak

In order to determine more accurately the γ-energies contributing to the peak in the region of 0·5 MeV., the γ-spectra of several samples were measured using a 1-in. cube sodium iodide (thallium) crystal which has a lower efficiency than the 3-in. crystal previously employed but an improved energy resolution (8 per cent at 0·66 MeV.). Part of the spectrum of our mid-February 1960 sample is shown in Fig. 2 and it will be seen that the peak at about 0·5 MeV. is complex. One component appears to be at an energy slightly higher than 0·50 MeV. This is probably due to rhodium-106 since in addition we have observed a small peak in the spectrum at 0·62 MeV. (Table 1). If it is assumed that rhodium-106 is present, the intensity of the 0·62 MeV. line can be used to estimate the contribution of the 0·51 MeV. line to the composite peak, since the relative intensity of these two lines is known from the reference standard. The composite peak can then be resolved into three components with maxima at about 0·515 MeV., 0·476±0·005 MeV. and about 0·43 MeV. Each of these components was found experimentally to have the same resolution as a single photo-peak of corresponding energy, which suggests that there are only three main components. For the reasons given below, the 0·476 MeV. line has been attributed to beryllium-7 and the 0·43 MeV. line to antimony-125.

Identification of Antimony-125

Antimony-125 is known to occur as a fission product[5], and has been reported in soil samples taken near the site of a nuclear explosion[6]. Its possible occurrence in ryegrass has also been suggested[6].

Apart from the correspondence of the 0·43 MeV. peak (Fig. 2) with the energy of the principal γ-line of antimony-125, we have detected an X-ray line of 0·027 MeV. which would be expected from the tellurium-125m daughter of antimony-125. The additional γ-lines of antimony-125 at 0·60 MeV. and 0·17 MeV. were masked by γ-lines from other fission products (barium-137m, rhodium-106 and cerium-144).

Evidence for the chemical identity of the nuclide responsible for the 0·43 MeV. γ-line was provided by addition of antimony carrier to a dust sample, subsequent separation of the antimony fraction and examination of this by γ-spectrometry. It may be noted that the material thought to be antimony-125 remained associated with the insoluble fraction after evaporation of the sample with a series of concentrated and dilute acids (perchloric, hydrochloric, hydrofluoric and nitric). This marked insolubility suggests that the activity was incorporated in highly inert, probably fused, particles. The insoluble matter was fused at 600°–650° C. with a mixture of equal parts of potassium hydroxide, potassium carbonate and potassium nitrate, and with the addition of 10 mgm. each of silver, antimony, cerium and strontium as carriers. The melt was leached with water and the lixiviate was found to contain the activity suspected of being antimony-125. After acidification with hydrochloric acid, the Group 1 precipitate was centrifuged out and the antimony recovered from the supernatant as the sulphide. The γ-spectrum (Fig. 3) of this antimony sulphide was identical with that of an antimony-125 reference source.

Identification of Beryllium-7

Beryllium-7 is known to occur naturally[7], being produced in the atmosphere by the interaction of

* X-ray line.

cosmic ray nucleons with nitrogen[8]. The energy of the main photopeak in the spectrum shown in Fig. 2 was found experimentally to correspond very closely with that of a beryllium-7 standard. However, a search of nuclear data tables[4] showed three other possible nuclides with principal γ-emissions in the energy-range of 0·46–0·49 MeV. and half-life between 10 and 100 days, namely tellurium-129m, hafnium-181, and curium-241. In view of the short half-lives (35–53 days) of all four nuclides it is unlikely that they would have been detectable if they had been products of nuclear explosions. It is improbable that beryllium-7 is produced in such explosions[9]. Moreover, the fact that beryllium-7 is continually produced in the atmosphere makes it the most probable of these four nuclides as being responsible for the 0·476 MeV. peak. The absence of additional γ- and X-ray energies which we would probably have detected from any of the other three nuclides adds weight to this view.

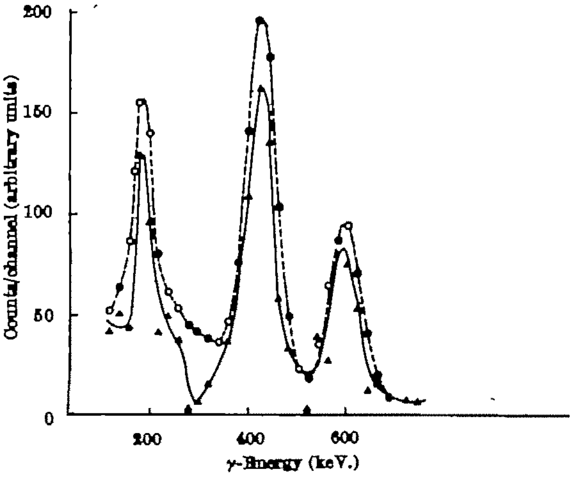

Fig. 3. Spectrum of antimony sulphide fraction (——) and reference standard of antimony-125 (- - - -)

We now turn to the chemical evidence for the identity of this material. An appropriate dust sample was digested with 50 per cent hydrochloric acid containing 10 mgm. of beryllium as carrier, and the 0·476 MeV. γ-line was found in the spectrum of the extract. The ready solubility of the activity is in marked contrast to that of antimony discussed above and accords with that to be expected from the mode of formation of beryllium-7, presumably as widely separated atoms. The solution was treated with an excess of ammonia to precipitate beryllium hydroxide and other hydroxides derived from elements such as aluminium and iron normally present in atmospheric dust[10]. The mixed hydroxides were extracted with 2·5 *N* sodium hydroxide to dissolve the beryllium and aluminium, leaving various hydroxides, notably that of iron, as an insoluble residue. The alkaline extract was next scavenged with hafnium by acidification, addition of hafnyl chloride and precipitation of hafnium hydroxide with excess alkali. Antimony and tellurium were removed together from the alkaline beryllium solution by successive acidification, addition of tellurium carrier, and precipitation of the sulphide. The beryllium was recovered from solution by precipitation with excess ammonia. A further scavenge, analagous to that with hafnium, was carried out using cerium. The hydroxide scavenges should have removed any curium that might be present.

In order to obtain the beryllium as a small source for β- and γ-counting, and to provide further purification, it was next separated from the associated aluminium. The supernatant from the cerium hydroxide precipitation was just acidified with hydrochloric acid and oxine reagent added, followed by ammonium acetate to complete precipitation of the aluminium. After removal of the aluminium oxinate by centri-

Table 2. RATIO OF SPECIFIC ACTIVITIES OF FISSION PRODUCTS, AT A TIME 18 MONTHS AFTER FISSION, CALCULATED FROM FISSION YIELD DATA FOR DIFFERENT TYPES OF FISSION

	$\frac{^{95}Zr + ^{95}Nb}{^{144}Ce}$	$\frac{^{106}Rh}{^{144}Ce}$	$\frac{^{125}Sb}{^{144}Ce}$	$\frac{^{137}Cs}{^{144}Ce}$	$\frac{^{90}Sr}{^{137}Cs}$
$^{235}U\ n_{th}$	0·15	0·07	0·004	0·11	0·93
$^{235}U\ n_f$	0·17	0·10	0·02	0·13	0·71
$^{239}Pu\ n_f$	0·17	1·7	0·06	0·17	0·36
$^{238}U\ n_f$	0·15	0·60	0·08	0·15	0·48
$^{235}U\ n_{14}$	0·17	0·95	0·24	0·17	0·51
$^{238}U\ n_{14}$	0·19	0·43	0·32	0·16	0·82
Experimental value Feb. 1960	<0·14	0·57	0·36	~0·14	—

n_{th}, thermal neutrons; n_f, fission spectrum neutrons; n_{14}, 14 MeV. neutrons.

fugation, the beryllium was precipitated with excess ammonia and mounted on a planchette. The γ-spectrum of this precipitate consisted solely of a line at 0·476 MeV., and was identical with that of a beryllium-7 reference standard. There was no measurable β-activity.

Relative Concentrations of Fission Products

Table 1 gives our observed concentrations in air of fission products associated with atmospheric dust during February 1960. Table 2 gives the relative activities of a number of nuclides eighteen months after fission, computed from published data[3] for different fissile materials and various neutron energies. It should be noted, however, that these ratios may need modification when applied in the case of a nuclear detonation. It will be seen that the ratios rhodium-106 : cerium-144 and antimony-125 : cerium-144 are sensitive to the type of fission process. Taken together, our experimental ratios (Table 2) agree best with the theoretical values for 14 MeV. fission of either uranium-235 or uranium-238, and in particular the high antimony concentrations which we have observed do not appear compatible with data for thermal neutron fission of uranium-235. The 14-MeV. neutrons are unlikely to be produced in a normal fission process, but they could be the result of a fusion reaction.

Concentration of Nuclides produced by Cosmic-rays Relative to Fission Products

Table 1 includes data for non-gaseous cosmic-ray produced nuclides. With the exception of beryllium-7, for which our measurements are quoted, the values are estimated from published concentrations in rainwater[11] on the assumption that the relative amounts in air and in rain are the same as for beryllium-7. It should be noted that the activity of beryllium-7 measured by us lies within the range of values 0·5–15 × 10^{-17} c./litre of air (1–30 atoms per litre) reported in Canada in 1956[12].

Table 3 contains some preliminary measurements of the specific activities of beryllium-7, rhodium-106, and antimony-125 in air samples collected during the early months of 1960. The seasonal rise in the beryllium-7 concentration is well known[12], and it is interesting to note that the fission-product concentrations are changing proportionally. This is demonstrated by the constancy of the ratios of antimony-125 : beryllium-7 and rhodium-106 : beryllium-7 activities.

Table 3. RHODIUM-106, ANTIMONY-125 AND BERYLLIUM-7 CONCENTRATIONS IN AIR SAMPLES

Mean collection date	Specific activity at time of collection in 10^{-17} c./litre			$\frac{^{106}Rh}{^{7}Be}$	$\frac{^{125}Sb}{^{7}Be}$
	^{7}Be	^{106}Rh	^{125}Sb		
2/1/60	1·4	0·26	0·12	0·19	0·09
30/1/60	1·6	0·24	0·18	0·15	0·11
18/2/60	2·2	0·41	0·27	0·19	0·12
4/3/60	3·4	0·48	0·32	0·14	0·09

It is noteworthy that by the beginning of 1960 the specific activity of fission products in the air at ground-level has fallen to a value comparable with that of naturally produced beryllium-7. The presence of beryllium-7 and antimony-125 complicates the estimation of the absolute amount of rhodium-106.

We wish to express our appreciation of the guidance and encouragement of Prof. W. V. Mayneord, in whose laboratories the work was carried out. We also wish to thank Dr. D. M. Taylor for help in preparing reference standards.

OBITUARIES

Dr. O. J. Silberrad

THE thinning ranks of those British chemists who were trained in Germany before the First World War were further diminished on June 17 by the death of Dr. Oswald John Silberrad at his home at Dryads' Hall, Loughton, Essex, at the age of eighty-two.

Silberrad was educated at Dean Close Memorial School, Cheltenham, the City and Guilds Technical College and the University of Würzburg. In 1902, at the early age of twenty-four, he became the first superintendent of the Chemical Research Department at Woolwich, which was under the ægis of the War Office. The new Department could claim to be the first to be created on modern lines specifically for armament research, although the Government organization that is now the Chemical Inspectorate had from its inception, half a century before, concerned itself with research into materials and explosives as well as with its primary function of inspection, and there was also a military experimental establishment concerned with ballistics.

The next four years were busy ones for the young superintendent. He went to Germany to study the comparable organizations there and designed the new laboratories and other equipment. He gathered a small but enthusiastic staff around him, including as his chief assistant and deputy Dr. R. C. Farmer, a fellow student at Würzburg who, with Dr. Godfrey Rotter (later director of explosives research in the establishment) and Dr. Harold Moore (later director, British Non-Ferrous Metals Research Association), among the seniors, survives him.

This period saw not only the discovery of tetryl and of the means of causing lyddite to detonate effectively in shell (it had conspicuously failed to do this in the Boer War), but also the introduction of T.N.T. into the Service and research into flashless and smokeless propellants and into steels for guns, shells and armour.

Silberrad reported to the Explosives Committee of the War Office, the chairman of which was Lord Rayleigh. In 1906, this Committee was disbanded, and in the same year Silberrad resigned, to become for the rest of his career a consulting research chemist and director of the Silberrad Research Laboratories. Had he remained in Government service, where he was such a distinguished pioneer of modern 'conventional' armaments research, there is no doubt that high office and honours could have been his.

His connexion with the armaments field was not, however, completely severed by his resignation, for in 1908 he was instrumental in providing the Admiralty with a special alloy capable of resisting the erosion suffered by the propellers of high-speed turbine-driven warships. Because of this erosion, the future of such vessels and liners had appeared somewhat problematical. Also, in conjunction with the firm of Hotchkiss, he worked on erosion-resisting steel for guns. Then, in the First World War he was honorary consulting chemist to the Ministry of Munitions. An outstanding achievement of this period was the successful process for manufacturing large charges of lyddite in iron instead of earthenware vessels. This enabled an improved synthesis, requiring a higher temperature than was practicable with the original method, to be used. He also turned his attention once more to flashless propellants and developed one for use in large howitzers.

Silberrad was a brilliant experimenter, and among other achievements of his fertile brain were a new chlorinating agent; a method of manufacturing isoprene; a new means of blasting petroleum wells; and the production of dyestuffs from T.N.T. residues.

I have very pleasant memories of a visit paid to Dryads' Hall and its adjoining laboratory in 1953, when I was collecting material for an article in connexion with the golden jubilee of Silberrad's old establishment, which by then had become the Armament Research Establishment of the Ministry of Supply. I was most hospitably and kindly received by Dr. and Mrs. Silberrad and given access to many old photographs and exhibits, over the assembly of which much trouble had been taken. This first, and unfortunately the last, personal contact with Dr. Silberrad left an impression of a man of intense mental vigour, drive and alertness, in spite of his seventy-five years and the fact that at the time he had not fully recovered from an attack of thrombosis.

Mrs. Silberrad survives her husband, with the only son of the marriage. J. S. Grew

Dr. Eric Ellenbogen

Dr. Ellenbogen was born in Vienna in 1921 and emigrated to the United States in 1940. He received his B.S. degree in chemistry from Indiana University in 1943. During 1943–46 he served with the United States Army in India and Burma. After his discharge, he studied at the Brooklyn Polytechnic Institute, working on inorganic plastics. In 1946 he entered Harvard University, received his M.A. in 1947 and his Ph.D. in 1949 under the guidance of Dr. J. L. Oncley. His dissertation dealt with the determination of the physical-chemical properties of insulin. From 1947 until 1949 he was a teaching assistant in the University Laboratory of Physical Chemistry Related to Medicine and Public Health, Harvard University. He was awarded a U.S. Public Health Service Postdoctorate Research Fellowship in 1949, which he held until 1951 in the Department of Biochemistry, Columbia University College of Physicians and Surgeons, under the sponsorship of the late Dr. E. Brand, studying the properties of tri- and tetrapeptides of specific steric configurations. In 1951 he was appointed research associate in the Department of Biochemistry and Nutrition, Graduate School of Public Health, University of Pittsburgh, and was promoted to assistant professor in 1952 and associate professor in 1957.

In 1959 he took leave from his post at the University of Pittsburgh to travel to the Weizmann Institute at Rehovot, Israel, to study with Prof. E. Katchalski, doing research on physical properties of certain polypeptides as models for certain proteins of biological significance. On the way back from the Weizmann Institute to the United States, Dr. Ellenbogen died of a coronary occlusion in Marseilles on May 29, 1960. He is survived by his wife Lois and two children.

He belonged to several American and British learned societies. His contributions to biochemistry include the study of the physical-chemical behaviour of insulin in dilute solution, the physical chemistry of specific polypeptides, the isolation of a non-insulin hypoglycaemic factor from pancreas, and the physical-chemical characterization of cardiac myosin.

Robert E. Olson

Prof. Eduard Reichenow

Eduard Reichenow, the eminent German protozoologist, died on March 23 in his seventy-seventh year. He was born in Berlin and was the product of a race versed in the natural sciences: his father, Anton, was a well-known ornithologist; his grandfather, Cabanis, a zoologist of note. He himself married Lilly Mudrow, of international fame in the field of malariology and who collaborated with him in his later work on avian malaria; her death three years ago cast a cloud over his life from which he was scarcely able to emerge.

Reichenow was educated at Schiller-Realgimnasium in Charlottenburg; later he entered the Universities of Heidelberg, Berlin and Munich, where he graduated in natural science.

He was associated with the Institute of Tropical Medicine, Hamburg, for most of his academic years, first as a student, for many years as director of its Department of Protozoology, and finally as its president. He travelled extensively in the pursuit of his work, and some of these journeys produced results of great scientific value—the discovery of malaria parasites in gorillas in the Cameroons, the elucidation of the complicated life-cycle of *Karyolysus* and other hæmogregarines in Spain, and the development of piroplasms in animals in East Africa. He investigated Chagas's disease in Venezuela, Mexico and Guatemala, sleeping sickness in Africa, marine biology at Rovigno and in the Baltic. In Germany itself he studied the intestinal protozoa of man, and with his wife he described in detail exoerythrocytic schizogony in *Plasmodium relictum* and other avian species of malaria parasites.

His careful observations on the cycle of piroplasms in the tick led him to conclude that this important group of protozoa belonged more probably to the Sarcodina than to the Sporozoa, among which they had hitherto been placed, and this new view may well act as a guide to their still unknown nature.

Reichenow's work and reputation were consolidated in his successive editions of Doflein's "Protozoology". Doflein's widow asked him to undertake this task and he produced the fifth edition in 1929; the sixth was not completed until 1952. The history of the latter provides a good illustration of his strength of character—the manuscript of the new edition was practically finished during the later years of the Second World War when a bomb fell on his house and the entire work was destroyed; undeterred, he recommenced the task and completed it a few years later.

Eduard Reichenow was a simple, quiet man, cautious and conservative in his scientific outlook, with an absence of flamboyance which did not detract from his ability to disentangle complicated problems in taxonomy or biology. His sound approach made him an ideal court of appeal, and he readily responded to requests for his opinion from all quarters of the globe. In these respects he resembled the English protozoologist, the late C. M. Wenyon, whose views on many problems coincided with his own.

He received many honours towards the end of his life: he was made an honorary member of the Society of Protozoologists, given an honorary doctorate of the University of Granada, and received special recognition from Munich on the occasion of the jubilee of his graduation.

The death of Reichenow has left a gap in the ranks of protozoologists which it will take long, if ever, to fill. He is survived by his daughter.

P. C. C. Garnham

NEWS and VIEWS

Physics at University College, London: Prof. J. Hamilton

Dr. J. Hamilton has been appointed to the newly created second chair of physics in University College, London, from October 1. Dr. Hamilton studied in the Queen's University, Belfast, and later began research at the Dublin Institute for Advanced Study under Heitler. During the War he was engaged on scientific work for the Royal Navy. After a brief appointment as lecturer in theoretical physics at the University of Manchester he moved to Cambridge in 1950 as lecturer in mathematics and was elected to a fellowship at Christ's College. Dr. Hamilton's interests have always lain on the physical side of mathematical physics, and during his time at Cambridge there has been a considerable strengthening in the amount of physics available to students reading the Mathematical Tripos. He has also succeeded in forming an active group of young workers imbued with his own pragmatic spirit. Under his leadership they have been applying modern dispersion relation techniques to low-energy pion physics with most interesting results. This characteristic emphasis on physical content is also to be found in his recent book, "The Theory of Elementary Particles", which contains valuable chapters on phenomenology as well as those dealing with the development of quantum field theory. The appointment of Dr. Hamilton to University College will strengthen considerably the theoretical side of a department which is already active in experimental high-energy nuclear physics.

Mechanical Engineering at Cardiff: Prof. S. P. Hutton

Dr. S. P. Hutton, who has been appointed to the new chair of mechanical engineering at the University College of South Wales and Monmouthshire, was educated at Calday Grange Grammar School and the University of Liverpool, where he graduated in 1941. After a period in industry, he joined the Aerodynamics Department of the Royal Aircraft Establishment in 1942 and was concerned with the design, development and use of high-speed wind tunnels for research on sub-sonic and trans-sonic aircraft. During 1945–46 he was in charge of similar research facilities in Germany. During 1946–49 he was a lecturer in fluid mechanics at the Imperial College of Science and Technology, where he was awarded his Ph.D. for research on water turbines and fans. Since 1949 he has been with the National Engineering Laboratory, East Kilbride, where he supervised the design and commissioning of the hydraulic machinery laboratory, eventually becoming head of the Fluid Mechanics Division in 1954. During 1951–52 he was sent by the Department of Scientific and Industrial Research to the Federal College of Technology, Zurich, where he carried out research under Profs. J. Ackeret and H. Gerber. Since March 1959 he has been deputy director of the National Engineering Laboratory responsible for industrial liaison. His research interests are in engineering fluid mechanics and his publications have been mainly concerned with flow measurement, fans, pumps and water turbines. He is a member of the Hydraulics Group Committee of the Institution of Mechanical Engineers and has been closely associated with the work of national and international standards organizations for water turbines. He has travelled widely and in 1956 was a member of the British Hydroelectric delegation to the U.S.S.R.

Chemical Technology at Edinburgh: Prof. P. H. Calderbank

Dr. P. H. Calderbank has been appointed to the chair of chemical technology in the University of Edinburgh in succession to Prof. K. G. Denbigh, who is going to the Imperial College of Science and Technology, London (*Nature*, January 2, 1960,

p. 14). The chair will be held concurrently with the headship of the Chemical Engineering Department of the Heriot-Watt College. Dr. Calderbank, who is forty-one years of age, was educated at Palmer's School, Essex, and at King's College, London, where he graduated in 1940 with first-class honours in chemistry. He then joined the Ministry of Supply (Explosives Division), where he was concerned with the maintenance and operation of heavy chemicals plant. Afterwards, he joined the firm of Bakelite, Ltd., in Birmingham, and engaged in several research and development projects connected with the manufacture of synthetic resins and polymers. In 1946, Dr. Calderbank was appointed lecturer in the Chemical Engineering Department at University College, London. At University College, Dr. Calderbank undertook research on the kinetics of reactions in fluidized beds of catalysts and was awarded the degree of Ph.D. In 1952, he was appointed professor of chemical engineering in the University of Toronto, where he was an active member of the American Institute of Chemical Engineers. He joined the Department of Scientific and Industrial Research in 1955, and, after a four-month study tour of American universities and research establishments, returned to the National Chemical Laboratory at Teddington, where he proceeded to form and direct a research group of chemical engineers. This research group was transferred to the Warren Spring Laboratory at Stevenage in 1958, and under Dr. Calderbank's direction evolved into a team of forty workers engaged in many aspects of chemical engineering and process development research. Dr. Calderbank is a member of the Institution of Chemical Engineers and has been the recipient of the John Millar Medal for chemistry and the senior Moulton Medal for chemical engineering.

Atomic Energy Research Establishment Appointments

DR. F. A. VICK, at present deputy director of the Atomic Energy Research Establishment, Harwell, has been appointed director. Dr. R. Spence, at present chief chemist, has been appointed deputy director, and Mr. L. Grainger, now head of the Metallurgy Division, has been appointed assistant director, with special responsibilities for applied research. The new appointments will take effect on September 1. Sir Basil Schonland continues as director of the Research Group, of which the Atomic Energy Research Establishment is a part.

Overseas Civil Service

Supplementary Pay and Allowances

IN statements made simultaneously in the House of Commons and in the House of Lords on July 28, it was announced that, subject to Parliamentary approval of the expenditure involved, the Government has decided to offer to take over, where necessary in Colonial territories, the inducement pay and allowances of overseas staff broadly on the lines of the arrangements followed in most technical assistance schemes. Although financial arrangements have already been reached with Nigeria and Sierra Leone in the light of their coming independence, it is also proposed to offer them agreements on those lines and it is intended to apply the arrangements to the High Commission territories. The effect of these proposals would be that, while the local Government would continue to bear the local rates of salary and other conditions of service, the British Government would bear the cost of supplementary pay and allowances which prove to be needed for overseas officers. The statement also recognized the direct responsibility of the Government to maintain stable administration throughout the years of change preceding self-government, while pressing forward with the recruitment and training of officers from the local population. These new arrangements, which will not cease with independence, demonstrate the importance which the Government still attaches to the maintenance of an efficient Overseas Civil Service. They would apply to all its 15,000 members, and the cost is estimated by the Secretary of State for the Colonies, Mr. Iain Macleod, at £10–20 million a year over ten years.

Agricultural and Scientific Research Overseas

IN reply to a question in the House of Lords on July 28, about agricultural and scientific research overseas, Lord Hailsham stated that both the Agricultural Research Council and the Department of Scientific and Industrial Research, like the Medical Research Council, have powers to maintain research workers in overseas territories where this is in the national interest, and the Department of Scientific and Industrial Research has some research staff in stations overseas. Both the Department and the Agricultural Research Council assist overseas territories by seconding staff for definite periods within the limits of their resources, and proposals for extending these arrangements are under examination. While it is considered that existing powers should be adequate for any such extension, Lord Hailsham said that the Government would not hesitate to seek additional powers if necessary.

India's First Agricultural University

THE Government of India has approved the establishment of an Agricultural University, the first of its kind to be planned in the country, at Rudrapur, in Uttar Pradesh. The University, a product of Indo-American co-operation, will be set up on the model of land grant colleges in the United States and is expected to cost Rs. 1.90 crores. The 16,000-acre Tarai State Farm will be attached to the University for use as a laboratory for research and experiment. The University will have three constituent colleges, an Agricultural College, a College of Animal Husbandry and Veterinary Science, and a College of Agricultural Engineering and Technology, and will train 325 students each year. It will provide comprehensive education in agriculture and allied subjects on the basis of an integrated system of teaching, and will pay particular attention to developing rural leadership and competence. The decision to establish the Agricultural University is to be welcomed, particularly at the present juncture, when considerable emphasis is being laid on self-sufficiency in food in the third Five-Year Plan.

Dental Research

THE Minister for Science, Lord Hailsham, stated in the House of Lords on July 27 that current annual expenditure on dental research of the Medical Research Council exceeds £35,000, and a considerable proportion of this sum is used to support investigations into the early development of dental caries at all ages, including the influence of biochemical and bacteriological factors, and the role of fluorine, calcium and other elements in tooth formation and resistance to decay. This expenditure amounts to about 1 per cent of the Council's total expenditure on medical research. He understood that the value of hand-produced sugar confectionery, including chocolate confectionery, in 1959, was £193 million and that the total consumption, based on prices paid by consumers, was £259 million. There is also some £750,000 a year spent on dental work in the Universities through the University Grants Committee, but he agreed that even taking into account work done in private institutions, the total effort falls far short of the country's needs. Lord Hailsham pointed out that one limiting factor is the availability of suitable research workers, and that the school dental service, betterment of which could do much to improve the dental health of the nation, is already handicapped by the shortage of dentists.

Output of Power in Great Britain

In his presidential address to the British Electrical Power Convention on May 30, Viscount Chandos, discussing "Electricity—the New Horizon", emphasized the great problems with which the increase in the capacity of generators faces the electricity manufacturers. The five main manufacturers of heavy-power plant in Great Britain had a capacity of not less than 7,000 MW. a year and the probable demand for new additions to plant for the grid might be put at about 2,750 MW. a year, leaving 4,250 MW. for export. The competitive power of Britain must be largely governed by competitive wages, and if these plants had to work appreciably below 7,000 MW. a year the industry would feel the pinch. To some extent, he pointed out, the amount of power that Britain has to sell for export must depend on the development of power in what are now described as under-developed countries, and in this connexion, while noting the general shortage of capital, Lord Chandos protested against the tendency to lend to uncredit-worthy countries. Besides avoiding inflation, Britain should seek to create new credit to match the ever-increasing sources of wealth which science and technology had to offer. Besides the new horizons in the generation of electricity, there were new horizons in its application. Its use in the home, the mounting use of fractional horse-power motors, its use in lighting and in communications, whether by transport or telephone, offered possibilities which it was as yet difficult to discern precisely, quite apart from the effect of such developments on all aspects of living. Finally, referring to the fact that the European Common Market would lead to some large industrial amalgamations, which would have at hand a larger domestic market than could ever be hoped to be found in Britain or even in the European Free Trade Area, Lord Chandos emphasized the danger of wasting or misusing technical man-power, instancing the waste involved in submitting four tenders for one nuclear power station. Without undermining competition, he suggested attempts should be made to co-operate more in fundamental research over a wide field and the industry should not be open to the charge of having half a dozen different research establishments, using perhaps twice the necessary technical effort, to extend the frontiers of our knowledge in relation to one particular part of the electrical industry.

The Swedish National Committee for Physics

The tenth general physics conference of the Swedish National Committee for Physics was held at the Royal Institute of Technology in Stockholm during June 1–3, 1959. In addition to a large number of contributed papers presented at twenty sessions, special guest lectures were delivered by H. Maier-Leibnitz (Munich), who spoke about the research programme of the Munich reactor, and by C. J. Gorter (Kamerlingh Onnes Laboratory, Leyden), who discussed the problem of orienting atomic nuclei at low temperatures. Introductory papers were given by O. Klein on the systematics of elementary particles and by H. Alfvén on plasma physics and magnetohydrodynamics. Abstracts of all the contributed papers are published in the March issue of *Arkiv for Physik* (16, 481; 1960). Most of the papers deal with aspects of plasma and nuclear physics, but several are concerned with the infra-red examination of semiconductors. A number of new instruments and devices are reported. At the University of Uppsala a high-precision curved quartz crystal gamma spectrometer of the Du Mond type has been constructed and used for precision measurements of the K- and L-levels in the heavier elements. Optical instruments include shearing interferometers for the examination of spectral line broadening (Royal Institute of Technology, Stockholm) and a photo-electric device for measuring spectrograms (University of Lund). At the Nobel Institute of Physics, Stockholm, a new method for measuring half-lives of excited states in the region $< 10^{-10}$ sec., based on the high-frequency deflexion of conversion electrons, has been tested. As a first step in a programme of development of large bubble chambers to be used at the 1,200-MeV. electron-synchrotron at the University of Lund, a 2-in. cylindrical chamber with vertical windows has been constructed. This University has also produced a cylindrical dose-rate meter for X-rays which is of small dimensions (2-mm. diameter) and which utilizes a p-n junction in a gallium arsenide semiconductor. The meter has a relatively low impedance and fast response, which makes it well suited for control measurements during X-ray therapy.

Plankton at Freetown, Sierra Leone

In work on the plankton of the estuary and the immediate offshore waters of the Sierra Leone River (Colonial Office. Fishery Publications, No. 13. Pp. iv+48. London: H.M. Stationery Office, 1960. 35s. net) Mr. V. Bainbridge was faced with a two-part problem imposed by the alternation of wet and dry seasons, the resulting conditions differing very considerably. Throughout the wet season there is a tendency towards a two-layered transport system, with brackish water flowing seawards on the surface and more saline water flowing into the estuary along the bottom. These conditions are, however, scarcely detectable in the dry season. During the wet season most of the phytoplankton within the estuary consisted of benthic forms and, at the offshore station, diatoms were relatively scarce. Very small numbers of diatoms at the offshore station during the dry season were coincident with a large standing crop of phytoplankton within the estuary, comparable in abundance with those found in Long Island Sound and the Rio de Vigo. The zooplankton species appeared to be subjected to a flushing out from the estuary during the wet season, with only a limited transport of a few species back into the estuary in the bottom current. Offshore, the largest variety of zooplankton species occurred late during the dry season, and fluctuations in species composition and abundance seemed to be associated with the oceanic currents. The very heavy standing crop of phytoplankton in the dry season did not appear to be utilized to anything like the full extent possible, either by zooplankton or by the phytoplankton-feeding clupeid fish *Ethmalosa dorsalis*. This fish, locally named the 'bonga', supports an important fishery in the estuary. The thorough examination of the sequence of events in this tropical estuarine area offers a very useful model for the approach to many similar problems, particularly in other areas where a fishery for *Ethmalosa* may be of local importance.

'Telex' and Inter-Library Communications

To arouse interest in the use of 'Telex' in inter-library communication a sub-committee of the Reference, Special and Information Section of the Library Association has compiled a directory listing 131 libraries in the United Kingdom with access to 'Telex' (Pp. ii+15. London: Library Association, 1960). The list was compiled on the basis of a questionnaire sent to the 198 members of the Association of Special Libraries and Information Bureaux, the firms of which are listed in the United Kingdom Telex Directory for October 1958, and to a few other organizations which had notified their interest in response to a notice in Aslib Proceedings of October 1959. The Directory is not for sale, but copies have been sent to public and special libraries, and it is hoped that the libraries listed will come to accept that 'Telex' can play a much greater part in library and information work in future, and that many more libraries will now consider it worth while to instal 'Telex'.

U.S. Translations of Russian Biological Publications

THE American Institute of Biological Sciences announces that it is now translating and publishing seven Russian research journals in biology. These translations are produced with support from the National Science Foundation. Hence the Institute is able to offer these translations at a fraction of their publication cost, with further price reduction to members of the Institute and to academic and non-profit libraries. The journals currently being translated are: *Doklady* (*Biological Sciences Section*); *Doklady* (*Botanical Sciences Section*); *Doklady* (*Biochemistry Section*); *Plant Physiology*; *Microbiology*; *Soviet Soil Science*; and *Entomological Review*. In addition to the translations of Russian biological journals, the Institute has instituted a separate programme of translation and publication of selected Russian monographs in biology. The monographs that have been published are: "Origins of Angiospermous Plants", by A. L. Takhtajan; "Problems in the Classification of Antagonists of Actinomycetes", by G. F. Gauze; "Marine Biology", Trudi Institute of Oceanology, Vol. 20, edited by B. N. Nikitin; "Arachnoidea", by A. A. Zakhvatkin; and "Arachnida", by B. I. Pomerantzev. Further information can be obtained from the American Institute of Biological Sciences, 2000 P Street, N.W., Washington 6, D.C.

Analytical Biochemistry

THE aim of *Analytical Biochemistry* (published by Academic Press, Inc., 1, No. 1, 1960; 15 dollars) is to publish work on new and improved methods of preparation, purification and analysis of substances which are of interest to biochemists, biophysicists, and others in related fields of experimental biology. It will include contributions dealing with qualitative as well as quantitative methods of analysis, and with the design of special apparatus and instruments. The first number (June 1960; pp. 95) contains, among others, communications on flame photometry, scintillation counting, separation of serum lipoproteins, and column analysis of nucleic acids. The editor is Alvin Nason, McCollum-Pratt Institute, Johns Hopkins University, Baltimore.

The Calouste Gulbenkian Foundation, Lisbon

THE trustees of the Calouste Gulbenkian Foundation, Lisbon, have announced the grants made during the first half of 1960. They include grants of up to £1,000 per annum for three years to British undergraduate scientific expeditions, given in consultation with the Royal Geographical Society, as follows: £250 to the Cambridge expedition to British Guiana; £250 towards the Oxford expedition to the Peruvian Andes; £140 to the Oxford Women's expedition to the Azores; £100 to the University of Oxford expedition to Cyrenaica; and £50 to the Wye College Exploration Society expedition to Morocco. Grants in aid of educational institutions include £10,000 to the Oxford Institute of Education and £2,700–£3,400 over two years to the Institute of Education, University of Durham. The grants made in aid of education in Great Britain and the Commonwealth total £23,085. In Portugal, £109,257 has been granted in aid of science and medicine, including the establishment of a centre for the treatment of alcoholism and addiction at the Institute of Psychiatry; campaigns against tuberculosis in Portuguese Guinea, and malaria in the Island of Santiago, Cape Verde Islands: a total of £23,278 has been given to educational institutions. £9,000 has been given for scholarships for Iraqi technicians to study at the National Laboratory of Civil Engineering, Lisbon. Grants have also been allocated to institutions in Brazil, France, Chile and Iran.

Abominable Snowmen

THE problem of the 'Abominable Snowmen' is discussed by S. V. Obruchev (*Priroda*, 10, 60; 1959), who presents a critical review of articles and books on this subject, beginning with Waddell's report of 1898 about the hairy wild man called 'Yeti' by the Tibetans. In the Soviet Press during 1957–59 there appeared a number of articles on this subject, especially on the possible presence of the 'Snowman' in the Pamirs. In 1958 a special expedition sent to the Pamirs to study this problem reported negatively, saying that the 'Snowman' existed only in local legends. Similar legends existed also in Mongolia. At the same time, numerous recent finds of teeth of a huge anthropoid ape—*Gigantopithecus*—in China suggest that the Tibetan 'Yeti' and the legendary 'Snowman' of the Pamirs and Mongolia may all refer to the former, or present-day but rare, presence of this type of ape in the high-altitude regions of the Himalayas and the Pamirs.

U.S.S.R. Fisheries Research by Submarine

VALUABLE oceanographic and fisheries work has been accomplished by a specially constructed submarine, *Severyanka*, as described by V. P. Zaitzev (*Priroda*, 8, 71; 1959). The submarine is provided with a viewing apparatus, several projectors, mechanical arms for collecting specimens from the bottom of the sea, echo-sounding apparatus and a cinema apparatus. The first sailing in the Barents Sea took place on December 14, 1958. Nine scientists were aboard. The second expedition took place during December 29, 1958–January 21, 1959, in the northern part of the Atlantic Ocean, and which covered some 4,000 nautical miles, aimed at the study of herring movements.

National Science Foundation Awards for Graduate Research Facilities

THE U.S. National Science Foundation has awarded grants totalling 2,153,710 dollars to fifty-four colleges and universities to improve graduate research laboratories. These grants are made on condition that the institution concerned provides at least 50 per cent of the funds needed. This permits assistance to a larger number of financially hard-pressed institutions and at the same time stimulates self-help to the greatest extent possible by the institution. Grants provide for construction, conversion or modernization of laboratory facilities.

The Institute of Metals: Annual Autumn Meeting

THE fifty-second annual autumn meeting of the Institute of Metals will take place at Bath during September 5–9. The meeting will be held partly at the Pump Room and partly at Guildhall. Included in the programme are such topics as: "Engineering Properties of Nickel-Base Alloys" and "Lubricants for Cold Rolling Aluminium" (September 5); "Recovery and Recrystallization" and "Engineering Properties of Alloys" (September 6); "The Relative Merits of Extrusion and Other Methods for the Manufacture of Bar, Rod and Wire-Rod" and "Magnesium Alloys for Fuel-Element Components" (September 8). The Autumn Lecture, on "Metals and the World of Engineering Structures", will be given by Sir Alfred Pugsley on September 9. Further information can be obtained from the Secretary, Institute of Metals, 17 Belgrave Square, London, S.W.1.

Announcements

DURING the past few years, many entomologists have inquired for insect suction traps which segregate the catch by dropping disks into the collecting tube. One firm may now agree to make the 9-in. Vent-Axia type (as described in *Annals of Applied Biology*, 37, 80; 38, 582) for approximately £100 each, complete with time switch, provided fifty orders are placed. Will those interested please communicate with Dr. C. G. Johnson, Rothamsted Experimental Station, Harpenden.

A STEERING Committee, originally appointed as a working party by the Faraday Society to consider the future of its work in the field of biophysics, has decided to launch a new and independent society to be known as the British Biophysical Society. The chairman and secretary of the Steering Committee are Prof. J. A. V. Butler and Dr. J. C. Kendrew respectively. The first scientific meeting of the new Society will take place in London in December. A more detailed announcement, giving information about the new Society and about its first meeting, and inviting inquiries from prospective members, will be made shortly.

SUPPLEMENTS 9 and 10 to the Index-Catalogue of Medical and Veterinary Zoology issued by the United States Department of Agriculture, June 1959 and April 1960, respectively, covering authors from A to Z, are now available (Supplement 9. Pp. 1+322. 1.25 dollars. Supplement 10. Pp. i+357. 1.25 dollars. Washington, D.C.: Government Printing Office, 1959 and 1960).

THE fifth annual conference of the British Society for the Philosophy of Science will be held at Wills Hall, Bristol, during September 23–25. Further information can be obtained from Dr. M. B. Hesse, Whipple Museum, Free School Lane, Cambridge.

AN International Congress on Experimental Mechanics will be held during November 1–3, 1961, in New York City. Further information can be obtained from Dr. Roscoe Guernsey, jun., General Engineering Laboratory, General Electric Company, Schenectady 5, New York.

THE twenty-first National Conference for the Preservation of the Countryside will be held at Weymouth during October 13–15. Further information can be obtained from the General Secretary, The Council for the Preservation of Rural England, 4 Hobart Place, London, S.W.1.

THE Metallurgy Society of France is organizing a meeting on "The Heat Treatment of Metals and Alloys" during October 17–21. The meeting will be held at la Maison de la Chimie, 28 bis, rue Saint-Dominique, Paris 7e. Further information can be obtained from the Secretary-General of the Society, 25 Rue de Clichy, Paris 9e.

THE tenth annual Instrument Symposium and Research Equipment Exhibit are to be held at the National Institutes of Health, Washington, D.C., during October 3–6 and October 4–7, respectively. Further information can be obtained from V. B. Davis, National Institutes of Health, Public Health Service, Bethesda 14, Maryland.

THE second International Plastics Exhibition will be held in Utrecht during October 19–26. Immediately preceding the Exhibition, an international congress on "The Technology of Plastics Processing" will be held in Amsterdam during October 17–19. The congress is sponsored by the Association for the Advancement of the Knowledge of Materials, the Royal Institute of Engineers, the Royal Netherlands Chemical Federation and the International Union of Pure and Applied Chemistry. Further information can be obtained from N. V. 't Raedthuys, Tesselschadestraat 5, Amsterdam.

ERRATUM. In the communication entitled "Synergetic Action of 2(*o*-Methoxyphenoxymethyl)-5-Oxazolidone on Morphine, Dihydrocodeine and Aminopyrine Analgesia", by E. Fischer, J. L. J. Szabó and M. Stamburgo, in *Nature* of June 11, p. 893, the authors state that they gave the chemical name of metoxadone incorrectly; it should read 5(*o*-methoxyphenoxymethyl)-2-oxazolidone in both title and first line of text.

GRADUATE SCHOOLS IN BRITISH UNIVERSITIES

A FEW weeks ago some highly interesting findings were published* of a Committee set up at Oxford last November "to consider and report on the accommodation, facilities and amenities in the University for graduates of this and other universities". The facts unearthed and the suggestions made show the fast-growing importance of Oxford as a centre of graduate study, particularly in the sciences, and the urgency of catering for the needs of this graduate population in new ways. Clearly, there is among Oxford dons a body of informed opinion conscious of practicable measures which might be taken to help to deal with the situation. But the report of the Committee has wider implications, too.

In 1939, out of some 5,000 students at Oxford, 520—or about 10 per cent—were reading for advanced degrees or diplomas; by 1960 this number had grown to 1,758 out of nearly 9,000, or about 20 per cent. Among the contributory factors to this development are the greatly increased numbers of grants for graduate work, the spread of the practice that scientists should take a research degree as a prelude to an industrial as well as an academic career, and the growing number of graduates from other universities who want to work at Oxford. Not merely have the modern universities much more than twice the student population that they had twenty years ago, but also Oxford and Cambridge have an unrivalled attractiveness both as places of learning and as prestige institutions ("above the social strife"). For many a graduate they have, consciously or unconsciously, something of the appeal of an Athenæum Club as well as of a university, short though they are of bedrooms and somewhat deficient in comforts. But so far neither has quite caught up with itself as a centre of graduate migration. Traditionally, they have been places at which to get a good undergraduate education, in a college, between the ages of eighteen and twenty-one or so. To-day, however, 92 per cent of Oxford's graduate students are more than twenty-two years of age, and a quarter of them more than twenty-five; 56 per cent come from other universities and are strangers to Oxford. Many are married, and of these the majority have their wives with them; an appreciable number have their children as well.

What is being done to meet the problems brought about by this state of affairs? The colleges provide some living accommodation, and a certain amount of wise advice is given about lodgings by the University Delegacy. But some of the lodgings are up to fifteen miles from Oxford itself and many stipulate "no children". The costs of good or even satisfactory accommodation are considerable; and outside the city there is much competition for it from Harwell and the surrounding air bases. The Committee believes that colleges ought to extend to unmarried graduates from other universities the privilege of spending at least their first year in college; and that the University ought to be bold in building flats for married couples and in making grants or loans to colleges to help them to convert houses for the use both of single and of married students.

But the graduate may find a roof to cover him and still remain a lonely man, with remarkably little to make him feel that he really belongs not merely to a laboratory or a department but also to the University—and this at a time when it may be of great importance to him to feel that he does so belong. He may, it is true, be a member of his college junior common room and go to lunch at Halifax House (424 of the 544 members of which, incidentally, are science graduates), but Halifax House suffers from inadequate buildings and from having nothing like enough money. (The Committee notes that "it is hoped that a new building for Halifax House will be included in the major building programme for 1964–68". One would have expected a note of greater urgency than this.) That graduate common rooms should be provided in the colleges is an admirable suggestion (only one college at present has such a room); so is the idea that 'study rooms' should be made available for the use of married graduates living out. It would be a great help, too, if the Delegacy of Lodgings made itself an active centre for relaying information affecting the residence outside college of members of the University. In the wealth of their information services, their skilfully compiled maps and brochures, their welcoming spirit efficiently incorporated into administrative terms, American universities certainly have something to teach both older and newer universities in Britain.

It has to be remembered that many of the men and women going from modern universities to Oxford and Cambridge as graduates will not have been resident before, either at school or in a university. This is a new start for them, an introduction to a wider world than they may have hitherto experienced. There may have been little possibility of finding in their honours school at 'Redbrick' the diverse and yet friendly community which a good college can be: and their time at 'Oxbridge'—in a fresh environment and with widening horizons—may find them ready to be newly and intimately receptive. But the defect of the British social system generally—and one which on occasion has applied to graduates going up to Oxford and Cambridge, whether from 'Redbrick' or from overseas—is that it leaves so many feeling that they are not quite within the inner circle. This defect is one which the Committee certainly had at the back of its mind. Its suggestions are essentially suggestions about how to make Oxford a more potent educational force in the lives of the graduates studying within it.

The report, however, has a more wide-spreading significance than for Oxford or 'Oxbridge'. Discernible here is a shift in attitude to the whole problem of the welfare and education of the graduate student and a recognition that if his continued studies are to give him not merely more knowledge and a further degree but also continued—and general—education he must be considered in his own right. The development of graduate schools of character and power is not dependent on the provision of laboratories, libraries, research amenities and supervision alone. This, so far, we have tended not sufficiently to acknowledge: all British universities remain unduly orientated to undergraduate needs. Yet the proportion of graduates will rise everywhere during the coming ten, twenty, thirty years; at some universities indeed (at the Imperial College of Science and Technology, London, for example) this policy is already fast being implemented.

---

* *Oxford University Gazette*, Supp. to Issue No. 3048 (June 16, 1960).

In a period when it is the done thing to marry and have children early, especially in the professional classes, and when a parental means test for the graduate student must before long become a thing of the past, is enough thought being given even in the modern universities to the problems involved? The idea of raising the percentage of graduates accommodated in halls of residence by a variety of means, including the addition of specially planned halls for graduates, must be considered. At some universities already a few houses have been admirably adapted to yield numbers of flats for graduate students (though sometimes at the risk of isolating the graduate further from the life of the university); and there are several active graduate students' councils. But the special needs and aptitudes of the graduate for a liberal education as well as for research training have been little regarded.

No doubt, Oxford and Cambridge are likely for some years to come to be magnets to graduates from elsewhere. But other universities, too, are attracting increasing numbers of students from outside themselves (including some from Oxford and Cambridge) and it is surely good that this should be so. Experience of two universities of differing temper and situation is often likely to be more enriching than of one only.

This pioneer report from Oxford is much to be welcomed—for its encouraging facing of local facts; for its wealth of practical ideas; but also for the example it gives other universities to set in motion corresponding investigations and to think thoughts of their own on their provision for the graduate within them.

W. R. NIBLETT

THE INDIAN OCEAN EXPEDITION

THE Special Committee on Oceanic Research, meeting in Copenhagen and Helsinki in July, was set up by the International Council of Scientific Unions in 1957, on the grounds that a new international scientific organization was needed to strengthen and promote research in marine science. It was to initiate joint programmes in consultation with the scientific unions and other organizations. The Committee met for the first time in the Woods Hole Oceanographic Institution in August 1958, and among other measures proposed a joint expedition to the Indian Ocean. It tried to choose the area most likely to attract the attention of scientists, where the work would appeal to world organizations which promote science and human welfare, and where better understanding is likely to prove most immediately useful to the surrounding countries. The Indian Ocean was an obvious choice[1].

The complete change-round of some of its currents in response to changes in wind direction will give physicists a fairly unique opportunity to study factors that influence water movements. Better knowledge of accompanying biological changes will improve our quantitative understanding of factors that control oceanic productivity. More detailed information about the distribution of fish—especially those that live in mid-ocean—in relation to the boundaries between currents and water layers should advance fisheries science and be readily usable. The Indian Ocean is an ocean with exceptional and prominent features. The exchange of energy between sea and air has much to do with the powerful monsoon winds, and any improvement in long-term forecasting of their onset and intensity will be very useful. We know there are large fish populations in mid-ocean, and records of tremendous mass mortalities occurring from time to time show that they live in critical marginal conditions. In geophysics, as in other aspects, the Indian Ocean offers attractive sites for research.

The justice of trying to boost science by pledging the anticipated success of a new scheme has rightly been questioned, and there is no doubt of the sincerity and good intentions of the editor of the privately circulated "Indian Ocean Bubble", which has voiced very reasonable opposition. He does not quite say that skilled young scientists who form the real backbone of our research laboratories will be swindled by the promoters, but he criticizes the prospectus which probably has promised too much, and sounds a clear warning about the ill effects of hindering new approaches and critical experiments by too much regimented and routine work. He makes chilling reference to recent books, "The Tragic History of the Sea", by C. R. Boxer — three accounts of disastrous early Indian Ocean expeditions—and "The South Sea Bubble", by John Carswell—a general popular account of the venture that he frightens us with.

The effort devoted to marine science is, however, in no way commensurate with the magnitude, variety and difficulty of the problems it has to solve, and after a hundred years work, much of it devoted to fishery problems, we have little idea about the distribution of current with depth in any ocean. We can quote another editor who hailed the departure of one of our greatest expeditions to the Southern Seas with the words, "We may wait, it is true, and consign to centuries to come, the toils, the glories and the hopes of science, or we may rely on an easy effort distributed over length of years for the accomplishment of much that vigorous exertion might now effect". He continues, "There are secrets of Nature we would fain see revealed while we yet live in the flesh—resources hidden in her fertile bosom for the well-being of man upon Earth we would fain see opened up for the use of the generation to which we belong. But if we would be enlightened by the one or benefited by the other, we must lay on power both moral and physical without grudging and without stint". He makes a more encouraging reference to the poet who wrote:

"Nimm die Zogernde zum Rath
Nicht zum Werkzeug deiner That"

These admonitions appeared in the *Quarterly Review* 120 years ago, and they are as timely and well-intentioned as the new cautions.

Extensive investigation of the South Atlantic Ocean by the German *Meteor* Expedition in 1925–27 did much to advance marine science, and there is little doubt that concerted effort with our new techniques in the Indian Ocean will meet with similar success provided we give ourselves as much time to learn from it, and avoid too much organization as a pattern of things to come. Perhaps the new venture follows too soon on the International Geophysical Year surveys, but the organization and the problems are being approached very carefully, by the research-minded scientists as well as those who see the need for some campaigning.

The planning and operating of programmes is being done by national committees for oceanic research. Growing interest in them has already sent research ships from the United States and the U.S.S.R. to the Indian Ocean, and useful observations are also being made by H.M. survey ships and Royal Australian Navy frigates. At the peak of activity, covering the north-easterly and south-westerly monsoons of 1962–63, there may be as many as twelve ships working in fairly close co-operation. It is expected that a ship from the United Kingdom will be there, and that she will play an effective part in the programme as well as serving as a base for scientists whose work is likely to be advanced by special observations in Indian Ocean conditions.

The Special Committee on Oceanic Research chose Copenhagen and Helsinki for its meetings because many marine scientists were already at Copenhagen to take part in intergovernmental discussions arranged by Unesco, and at Helsinki to participate in the scientific meetings of the International Union of Geodesy and Geophysics. There is much careful and detailed work to do. Those taking part will be heartened by the recent announcement from the White House of active support to the U.S. contribution for which the National Academy of Sciences–National Research Council is scientifically responsible.

G. E. R. DEACON

WATER RESOURCES IN THE UNITED STATES

THE pressure of growing populations with rising standards of living increasingly brings water into focus as a basic raw material in need of both study and conservation. Nowhere is this realized more fully than in the United States, where development in a wide range of activities is at present limited by water supplies. As a result of Senate Resolution No. 48 of the eighty-sixth Congress of the United States a Select Committee on National Water Resources was set up in 1959 to study the extent and character of water resources activities required to provide the future quantity and quality of water needed for all segments of the economy in the United States.

Headed by Senator Robert S. Kerr from Oklahoma, this Committee has now been at work during the past year and has within a short space of time produced an impressive array of reports on a wide variety of hydrological topics*. Although confined to the United States, many of these reports have relevance to water problems that the United Kingdom and the Commonwealth face, and it is the aim of this review to indicate the coverage of the reports so far available together with their main conclusions. The speed with which the Select Committee has produced a great body of useful basic material is notable, and this has been achieved by the Committee calling upon existing authorities and organizations to provide the appropriate hydrological information.

As a result the reports fall into a number of natural groups largely related to the reporting department, the stage being set by No. 2, where the Legislative Reference Service of the Library of Congress reviews and summarizes the work of more than 20 commissions or committees which have investigated national water policies and problems in the United States during the past fifty years. With few exceptions previous study groups have paid little attention to the questions which the Senate has placed before the present Select Committee; notably, "How much water development is needed? When is it needed? Where is it needed? What should be the pattern of water development? What amounts of water will be required in relation to various levels of population and economic activity? What are the economic limits of water development?"

One of the first authorities that the Committee turned to for basic information was the Geological Survey; this department has prepared reports Nos. 3 and 4 dealing with the national water resources, both surface and underground, and related problems. In addition to furnishing quantitative information showing the use of water, the availability of water, and the amount of storage required to maintain certain rates of river-flow, report No. 3 identifies and discusses water problems in the fields of supply, variability, distribution, natural quality, pollution and floods. The report indicates that almost every part of the United States faces current or potential water problems. An estimated water use in 1960 of 250 thousand million gallons of fresh water a day is projected to rise to 600 thousand million gallons a day by 1980. This fortunately still falls considerably short of the estimated manageable supply of 1,160 thousand million gallons a day, but it does mean that in many areas much water will have to be used over and over again and that pollution abatement becomes critical. Report No. 4 presents in tabular and map form the surface water resources of each State. Data on average, maximum, and minimum discharges in cubic feet per second, and average annual run-off in acre-feet at key-points within each State are given, together with a very interesting set of maps showing comparative river-flows. This report really summarizes in a most effective way the annual surface water supply papers of the United States.

---

* Reports available in June 1960 and printed for the use of the Select Committee on National Water Resources of the United States Senate pursuant to Senate Resolution No. 48 of the Eighty-Sixth Congress. Government Printing Office, Washington.

No. 2, Reviews of National Water Resources during the Past Fifty Years, October 1959; No. 3, National Water Resources and Problems January 1960; No. 4, Surface Water Resources of the United States, January 1960; No. 7, Future Water Requirements for Municipal Use, January 1960; No. 9, Pollution Abatement, January 1960; No. 12, Land and Water Potentials and Future Requirements for Water, December 1959; No. 13, Estimated Water Requirements for Agricultural Purposes and their Effects on Water Supplies, December 1959; No. 16, Flood Problems and Management in the Tennessee River Basin, December 1959; No. 19, Water Resources of Alaska, January 1960; No. 20, Water Resources of Hawaii, January 1960; No. 21, Evapo-Transpiration Reduction, February 1960; No. 22, Weather Modification, January 1960; No. 23, Evaporation Reduction and Seepage Control, December 1959; No. 24, Water Quality Management, February 1960; No. 25, River Forecasting and Hydrometeorological Analysis, November 1959; No. 26, Saline Water Conversion, November 1959; No. 27, Application and Effects of Nuclear Energy, December 1959, No. 28, Water Resources Research Needs, February 1960.

Reports Nos. 7, 9 and 24 emanate from the Department of Health, Education and Welfare ; these deal with the future water requirements for municipal use, pollution abatement, and water quality management respectively. At the turn of the century about 30 million people in the United States had a municipal water supply and were using some 3 thousand million gallons a day. In 1954, the number supplied had increased to more than 100 million people and these were using 16 thousand million gallons of water daily. This is an average rate of nearly 150 gallons *per capita* a day with maxima of more than 200 gallons a day per person in some towns. These figures of course include both trade and domestic use. Report No. 7 shows that with medium rates of growth of population this level of water consumption will probably rise to 29 thousand million gallons a day by 1980 and 43 thousand million gallons a day by the year 2000. With a high rate of population increase the figures would be 33 thousand millions by 1980 and 58 thousand millions by the year 2000. Assuming that certain stimulants of municipal use continue to occur and taking a maximum population increase, a ceiling of 43 thousand millions by 1980 and 88 thousand million by the year 2000 is theoretically possible. Daily consumption *per capita* might then be of the order of 225 gallons. If cities are to continue to supply their residents with adequate supplies of clean fresh-water much forethought is clearly going to be necessary.

Report No. 9 from the same department deals with pollution, and directs attention clearly to the magnitude of the problem which confronts the United States in its search for clean water. In addition to the normal problems of disposal of sewage and ordinary industrial wastes, many new types of pollution have recently appeared. Synthetic organic chemicals, radioactive substances and newly identified viruses and other disease-producing micro-organisms are the problems of principal concern.

The third report from this Department, No. 24 in the series, deals with water quality management. This discusses water quality and quantity requirements for various purposes, the limitations of streams as waste carriers, and the economics of water pollution. It points out that the growing demands for water and limitations on developable supplies inevitably imply a greater re-use of river-flows, and it further emphasizes that many areas are rapidly running out of clean water.

The next group of reports, Nos. 12, 13 and 28, have been prepared by the Department of Agriculture, and these deal respectively with land and water potentials and future requirements for water, estimated requirements of water for agricultural purposes, and the needs of water resources research. Report No. 12 confirms that the use of water for agricultural purposes is the largest consumer of water in the United States, even though in recent years withdrawals of water for industrial purposes have exceeded those for irrigation. Generally, however, more than half the water withdrawn for irrigation is consumed by evaporation and transpiration, while less than a tenth of the water withdrawn for industrial purposes is lost. Agriculture also becomes of increasing significance in the water problem because of the growing trends in the United States to irrigate the humid areas as a means of increasing yields of crops. The report shows that the diversion and storage of water for irrigation in 1954 was 195 million acre-feet, of which 115 million acre-feet were actually used for irrigation. On the basis of projections of medium-level populations the Department of Agriculture estimates that requirements of water for irrigation in 1980 will amount to 181 million acre-feet for storage and diversion with 114 million acre-feet actually used for irrigation. This somewhat surprising and welcome reduction emerges as a result of assuming the application of known improved methods of water management. Failing, however, the adoption of these improved methods of storing, transporting and using irrigation water, enormous additional amounts of water would be required.

In addition to the direct use of water for agricultural production there are a number of other programmes in the United States for the conservation and development of agricultural land which affect water resources. These include the run-off and water-flow retardation schemes, soil erosion prevention, and watershed improvement. Report No. 13 deals with the implications of these : at present programmes for land treatment have been put into effect on some 18 per cent of the crop-land, pastures and woodlands. This should increase to 32 per cent by 1980 and 52 per cent by the year 2000. These programmes will, it is thought, deplete downstream flows by 4·5 million acre-feet in 1980 and by 7·8 million acre-feet in the year 2000. These amounts are small in comparison with the requirements of irrigated agriculture and are not thought to be problematical. Report No. 28, also prepared by the Department of Agriculture, lists the research which will be needed if the best use of water is to be made in the production of essential agricultural and forest products. This report shows a welcome awareness of the importance of water as a prime raw material worthy of care and conservation.

The next group of reports, Nos. 22 and 25, emanate from the United States Weather Bureau and deal with weather modification, river forecasting and hydrometeorological analysis. In the broadest sense weather modification includes all man-made changes in natural conditions of weather and climate. It applies to a wide variety of atmospheric phenomena ranging in scale from micro- to macro-conditions. Report No. 22, however, deals primarily with cloud modification as a means for increasing rainfall. As only 5–15 per cent of the available moisture in a cloud system reaches the ground during a rainstorm, it is obvious that even a slight increase in the amount of precipitation could have a tremendous effect on water supplies. It has been held that this possibility therefore justifies the very considerable expense that has so far been incurred in artificial rain-making. To date, however, the Weather Bureau has had to admit that much uncertainty still remains in the results of cloud seeding and in the practical utility of present methods of artificially increasing rainfall. The Weather Bureau also has the responsibility of forecasting river-flows for the purpose of reducing flood damage and the prevention of loss of life from floods, and report No. 25 deals with future needs and possibilities for improvements in this service as a means of increasing the usefulness of available water supplies.

A further group of reports, Nos. 19–21, 23 and 26, emanate from the Department of the Interior. Nos. 19 and 20 are straightforward accounts of the water resources of Alaska and Hawaii respectively. These two States have been considered separately from the continuous area of the United States as so many of their water problems are different. The report on Alaska shows that four main problems will hinder water supply development in the far north: these are the winter freeze and permafrost, the presence of glacial flour, impervious consolidated rocks limiting ground-water storage, and problems of waste disposal in the winter months. It is interesting to note that irrigation is being employed in Alaska and that eventually this should grow to 50,000 acres. The potential of water-power is enormous and more than 13 million kW. could be developed at some 168 sites. In Hawaii the main problem appears to be the unequal distribution in both time and place of the precipitation, and this produces recurring water shortages despite the abundant rainfall. Immediate problems are not, however, incapable of solution.

Reports Nos. 21 and 23 may be taken together as these deal respectively with evapo-transpiration reduction, and evaporation reduction and seepage control. Evapo-transpiration is the transfer of water to the atmosphere from plants and other surfaces as a result of normal evaporation of precipitation, and also transpiration, which is the release of water vapour to the atmosphere in the process of photosynthesis. The Department of the Interior reports that opportunities for improved yields of water through management of vegetation appear favourable on some 15 per cent of the area of 17 western States; with a possibility of increasing water-yields in amounts ranging from about 1 to 6 inches in certain forest areas of heavy precipitation to as low as 0·25 in. in the pinon-juniper regions. No increase at all is possible on the semi-arid lands covered with grass and shrub which make up the greater portion of the south-west United States. The Department has also investigated the effect of losses from phreatophytes, the water-loving 'well plants' which cause a major loss of water along rivers in the western States. These cover some 16 million acres and discharge 20–25 million acre-feet of water into the atmosphere annually. By controlling the phreatophytes it should be possible to save some 6 million acre-feet of water by 1960 and up to 12 million acre-feet by the year 2000. Much water is also lost from irrigation works by seepage and evaporation, and it is estimated that improvements in irrigation water conveyance works could save up to 4·5 million acre-feet by 1980.

Report No. 26 is concerned with the increasingly important topic of saline water conversion. The search for means of tapping this obvious unlimited source of water has taxed the ingenuity of man for many centuries, and practical methods for desalinization of ocean water in small quantities have been used on ships for more than a century. Attention has more recently been turned to the construction of large-scale land-based plants. A programme of research was launched in the United States in 1952 and further enlarged in 1955. In 1958 Congress authorized the construction of large-scale experimental demonstration plants, and this programme is now under way. In spite of rising prices the cost of converting sea and brackish water to fresh is continually being lowered. Before the Second World War it stood at 4 dollars upwards per thousand gallons: the new experimental plants should be converting saline water to fresh for less than a dollar per thousand gallons, while processes now in the laboratory stage give promise of conversion-rates below 50 cents per thousand gallons. This report details all the current and proposed fundamental research, and is a real mine of information for those concerned with this problem.

Finally, there are two other reports of interest: from the Tennessee Valley Authority comes No. 16 on flood problems and management in the Tennessee River Basin, and from the Atomic Energy Commission there is No. 26 dealing with the application and effects of nuclear energy. The flood problem is the converse of the problem of water shortage and, like the United Kingdom, the United States has had in most parts a multiplicity of authorities dealing separately with problems which are really integrated. Programmes for run-off and water-flow retardation and prevention of soil erosion have been the responsibility of the Department of Agriculture, downstream flood-control works have been in charge of the Corps of Engineers: reclamation work falls to the Bureau of Reclamation. Other authorities are responsible for the development of power, public water supply, irrigation and so on. In the Tennessee River Basin, however, there is an example of an integrated river basin development which is a model of its kind. Here the Authority covers an area of about 40,000 sq. miles and has in its charge all aspects of the hydrological cycle. It was therefore invited to present to the Select Committee any suggestions as to how its experience might be applied to the major water problem in the United States. In report No. 16 it has some interesting recommendations, more particularly in the sphere of development control in flood plain areas.

The particular water needs and problems arising from the development of atomic energy are dealt with in report No. 27 prepared by the Atomic Energy Commission. It is not thought that the requirements and applications of nuclear technology will have any major effect or impact on the development of water resources up to 1980, but the need to recognize the importance of control of water-dispersed waste radioactive products is stressed.

It will be clear that the 600 pages and innumerable diagrams, maps and tables in these 18 reports present a unique and up-to-date picture of the water problems facing the United States. The willingness to look ahead, initially to 1980 and then beyond to the year 2000, at low-, medium- and high-level population densities reveals an awareness of the increasing importance of water in the future; and of the necessity for the present generation to plan for the water needs of the next. In contrast, the British Central Advisory Water Committee in its recent reports was not prepared to look in any detail beyond 1965—which is almost upon us already. A comparison between the two sets of reports also reveals a quite different attitude of mind and approach to essentially the same problems—notably in the case of irrigation in the humid areas. It is to be hoped that the United States Senate Committee reports will become known in Great Britain to all those concerned with the great variety of aspects of the hydrological cycle; notably watershed management, storage of water, supply of water, control of the quality of water, pollution, saline conversion, and irrigation. The reports throw much new light on the increasingly important problem of water conservation.

W. G. V. BALCHIN

SHORTAGES OF SCIENTIFIC PERSONNEL IN EUROPEAN COUNTRIES IN PROCESS OF DEVELOPMENT

THE shortage of scientific personnel is common to all European countries, even those which have a long tradition of scientific and technical development backed by powerful resources. Industrialized countries face ever-increasing requirements, while countries which are primarily agricultural and commercial now feel the need to build up their industrial potential in order to compete with the rest of Europe and raise their standard of living.

For such countries the shortage of scientific personnel is particularly acute and raises problems which are most urgent. Chief of these, according to Rector Capelle, director-general of the Institut National des Sciences appliquées, in a recent issue of *European Productivity* (No. 35; April 1960), are: training of teachers of science and technical subjects; broadening of secondary education to include technical subjects; training of engineers; development of scientific research; and the development of university-industry relations.

Industry's demand for scientists and technicians and the generous salaries offered are frequently a severe handicap to the recruitment of science teachers. Teachers' salaries must be raised if the necessary teachers of high calibre are to be found for the rising school population. This applies not only to secondary schools and technical colleges but also to the universities themselves, where too often a professor's salary at the end of his career is no more than that offered to his students on entering industry. A further demand for teachers comes from industry itself, where the old system of training skilled workers and technicians on the job must be supplemented by proper training courses providing the appropriate general education at each level.

In order to persuade more and more young people to become technicians or engineers, and to attract children from families obsessed with the idea of classical education, the traditional secondary education should be broadened to include technical subjects laying the foundations of a technical humanism supplementing, and in no way conflicting, with traditional humanism. In all secondary education, the laboratory and the workshop should now be used as instruments of learning in the same way as books, which still have too much of a monopoly.

In countries in process of development, engineers are trained to a high level and in physical conditions in no way inferior to those prevailing in countries with a long-established technological tradition. Technical faculties or universities training engineers are compelled to make a strict selection of candidates, but this is a good guarantee of success. Many students who cannot find a place in the higher educational establishments of their own country go to a foreign technical university. This additional supply of engineers—sometimes as much as 50 per cent—is not always appreciated.

The methodical increase of means of production implies making provision for research. It might seem enough to leave the responsibility for research to the countries best equipped for it. This would in the end be detrimental to young industries. The organization of scientific research will become a vital necessity for all countries and will call for the combination of all human and material resources; the Government, the universities and industry must all co-operate, and here the university can play a leading part without any loss of dignity or independence.

Applied scientific research is one of the links to be established between universities and industry, two worlds which are much too far apart in most countries in process of development. Industry should not be governed purely by a shopkeeper mentality.

EAST AFRICAN VIRUS RESEARCH INSTITUTE, ENTEBBE

THE report of the East African Virus Research Institute for July, 1958–June, 1959 by the acting director, J. D. Gillett, shows that the approach to virus studies is still essentially ecological—using the word in its widest sense to cover interaction between virus host and environment (Pp. ii+49. (Nairobi: Government Printer, 1960.) 5s.). Attention has again been confined to those viruses which are transmitted to man by arthropods; 60 different viruses are now known or suspected of being arthropod borne. Mosquitoes are involved or suspected in the transmission of no less than 48 of these, and man has been implicated in 47 of them. Twenty-six of these viruses have been found in Africa, 14 of them coming from East Africa itself. Eleven of the 14 East African viruses were originally isolated in the Institute, three of them during the current year.

The isolation of viruses from the living vertebrate host, including man, is often missed because of the transient nature of the viræmia. Nevertheless, in addition to several strains isolated during an outbreak of yellow fever in the Congo, five isolations have been made in East Africa from man; three of these in the period under review were from members of the Institute staff. Three of the five East African isolates appear to be new agents, or at least new strains. One of the others was an accidental laboratory infection of Wesselbron virus, and opportunity was taken of keeping full clinical and physiological records of the course of this very unpleasant disease.

More than 20,000 wild mosquitoes were caught and processed in the laboratory, but no virus isolations were made. This is the second year in which this usually fruitful source of virus has been unproductive.

The work started the previous year on a possible vaccine against Nairobi sheep disease, the virus of which apparently involves man as well as sheep, has been further developed. The first field-trial with the new experimental vaccine carried out in collaboration with the East African Trypanosomiasis Research Organization at Sukulu has fully justified earlier hopes.

Antibody surveys in local residents have been extended by increasing the number of sera tested and by widening the spectrum of viruses used. Positive reactions have been found in all but one of the ten agents used. Surveys of birds were started again, but no positive results have been obtained.

Results of the antibody surveys on a large number of hippopotamus sera have given unexpected results, and are difficult to interpret. A high proportion of the sera has given positive neutralization against all five viruses tested.

Laboratory studies on the viruses of Rift Valley fever, encephalomyocarditis, Semliki Forest fever and yellow fever have been carried out in rodents, primates, birds and insects respectively.

The outstanding event of the year was the completion of the 120-ft. steel tower in the Mpanga Forest. This has brought about a considerable expansion in the work on the biology of mosquitoes and other blood-sucking flying insects.

The successful transmission of virus by mosquitoes depends partly on an adequate extrinsic incubation period during which the virus multiplies in the insect and reaches the salivary glands. Thus, if a species of mosquito is short-lived in Nature, it is unlikely to take part in virus transmission, even though it may be an efficient transmitter in the laboratory. It is of great importance to be able to tell the age of wild-caught mosquitoes. While this can be done in certain species with considerable accuracy by dissection, it would be an advantage if such determination could be correlated with external features. Work on this problem, started in 1951, was taken up again two years ago and has been continued and extended.

THE CARNEGIE UNITED KINGDOM TRUST

THE forty-sixth annual report of the Carnegie United Kingdom Trust, covering the year 1959, the fourth of the present quinquennium, is largely an account of the working out of ideas, schemes and projects approved and announced some time ago*. During the year, however, the Trustees have noted signs of voluntary work being richly leavened out of all proportion to the contributions made by the Trust, but while, as public responsibility for education at all stages has increased, the opportunities for the Trust have correspondingly diminished, the Trustees continue to find voluntary efforts that are unsupported, or inadequately supported from public funds. The quinquennial provision of £50,000 in aid of museums and art gallery development has been absorbed proportionately over the four years to the end of 1959, and it seems likely that the uncommitted balance will suffice to meet claims upon it in the remaining period. Assistance to the Museums Association was continued, but last year's grant was reduced to £1,200, in the expectation that the Association will thereby be encouraged to become self-supporting. A gratifying feature was the number of museums, earlier grant-aided by the Trust, that put in hand substantial schemes for enhancing the display of their collections and for improving their services generally.

Much of the work of the Museums Joint Committee is concerned with improved museum lay-out, and during the year a further twenty reports were commissioned in connexion with applications for grants for methods whereby collections may be more attractively and dynamically displayed; and arising from the recommendations of these and earlier reports grants totalling £9,065 were offered to seventeen museums and art galleries. After considering in consultation with the Ministry of Works, the Ancient Monuments Board, the National Museum of Antiquities and the Society of Antiquaries, a proposition to rebuild a medieval structure at the north-east of the main block of Iona Cathedral to serve as a lapidarium to house the numerous historical sculptures in and around the Cathedral, the Trustees approved a grant of £6,000 to rebuild the medieval infirmary to be used eventually as a museum of cathedral treasures, but meanwhile to house the most important stones until a permanent lapidarium is provided.

Up to the end of 1959 the Trust had received 1,287 applications from the committees of pre-war village halls, serving small rural communities, for assistance in meeting the cost of renovating and equipping their premises, and of these, 1,031, representing a total commitment of £131,588, had by that date been successful. In consultation with the Scottish Council of Social Service the Trustees have also adopted a modified scheme which will make it easier for such small communities as those on remote islands off the coast of Scotland to embark on the improvement of their halls. Grants totalling £9,190 were promised during the year towards the building of five new village halls in Eire, and under the scheme for providing film projectors and screens for the use of crofting communities, equipment was installed or is about to be installed in thirteen places in the Highlands. A review of progress in the seven schemes for extending into rural areas the advice services available in urban districts through the Citizens' Advice Bureaux, indicates that the experiments have been worth while and the services will be continued when the Trust's grant terminates. The committee set up to study and discuss the development problems of new communities also made satisfactory progress, and the report emphasizes the primary need for leadership in such communities. The National Federation of Community Associations was promised a grant of £5,500 to finance a two-year project for training full-time community centre wardens. The first group of trainees completed their course in March 1959, and a second group started a similar course in the autumn of 1959. Annual grants were also made to the various national councils of social service, and a grant of £6,500 in annual instalments towards the establishment of the North Ireland Association for Mental Health, a like amount being provided by the Government of Northern Ireland. A grant of £2,500 over the first two years was offered towards the cost of an experimental publicity campaign for three years by the Liverpool United Voluntary Organization for the maintenance of voluntary social service.

In education, the Trust supported 173 bursaries, totalling £454, with the Field Studies Council and the Scottish Field Studies Association. Most of the grants in 1959 for field work in archæology were towards the fees and expenses of visiting experts acting as directors of excavations and other field work. Up to 1958 astronomy was the only purely physical science which had qualified for inclusion in the Trust's scheme for the development of amateur scientific activities out of doors. During 1959 the Advisory Committee recommended the inclusion of meteorology, and the Trust has made a grant of £1,000 over 1959 and 1960 towards a scheme prepared by the Royal Meteorological Society. The work during the first season of the Conservation Corps showed a substantial untapped reservoir of potential public service, and the Trust is meeting the cost of a scheme for providing in the Queen Elizabeth Forest Park a hill-top view-point with indicator and shelter at the highest point on Duke's road in the Trossachs and a hill-top pavilion near Aberfoyle. A grant of £12,750 was made to the Homecrafts Advisory Association for the Disabled, established by the Central Council for the Care of Cripples, to finance the development of the Association over five years.

* Carnegie United Kingdom Trust. 46th Annual Report, 1959. Pp. 50. (Dunfermline: Carnegie United Kingdom Trust, 1960.)

THE ONTARIO RESEARCH FOUNDATION

THE annual report of the Ontario Research Foundation for 1959 includes a list of papers published during the year and a list of the professional and technical staff (Pp. 40. Toronto: Ontario Research Foundation, 1960). Appended are lists of grants for postgraduate studies in science, 1959–60.

In biochemistry, work continued on long-term projects such as the effect of dietary fats on blood cholesterol-levels, the development of a self-contained domestic sewage unit, the evaluation of spruce bark as a source of tanning materials and drilling mud additives, and the reclamation of purified cellulose from waste paper. In chemistry most of the long-term research and industrial fellowships in wood chemistry were concerned with lignin, including work on the chemistry of vanillin and related compounds, development of a new method for the removal of sugars, based on the solubility in organic solvents of a tertiary amine salt of the lignosulphonates. A reasonably clear understanding of the tanning potentialities of lignin has been obtained and no further work as a major project is contemplated. The activities and staff of the Physical Chemistry Division increased considerably, and basic research was continued on stereo-specific catalysts for the polmerization of 1-butene.

In engineering and metallurgy ore dressing work materially increased, and basic research included trials on five iron ores of an improved flash roaster, evaluation of means for improving electrostatic separating machines and a study of the fundamental properties of magnetites and hæmatites. A major project in process metallurgy was a continuation of the jet smelting programme, and basic research in physical metallurgy was largely concerned with a fundamental study of the fatigue of metals. A possible method for measuring residual microstresses was indicated as well as for studying the ductile–brittle transition zone in certain alloys. An extensive examination of steel and cast-iron mains and services formed part of a more general investigation of safety in natural gas distribution systems for the Ontario Government.

In parasitology, research comprised a survey of parasites of trout in certain lakes in Algonquin Park and an investigation of the mode of transmission of two tapeworms in trout; investigation of selected roundworms; investigation of life histories of blood parasites of birds and the possibilities of their transfer; and blood-sucking insects in relation to their feeding habits and the importance of insects in transmitting blood parasites.

In the Physics Department, basic research centred around the production and application of electron beams. Development of the atmospheric electron probe with X-ray spectrometer continued. An optical bench for investigating electron beams of wide cross-section was designed and its construction almost completed, and construction of a fluorescent probe for the University of Toronto Institute of Aerophysics was completed. In physiography an intimate knowledge of the soils and climate of Ontario continues to be built up, and in studies of crops a heat index was derived from growth-chamber results in Indiana and applied to thirty years records at the Central Experimental Farm at Ottawa. In textiles, continued research on wool sought new and improved methods of increasing resistance to alkali and reducing agents and of lowering felting properties. In the modification of cellulose fibres to improve crease resistance and fabric stability good progress has been made with the use of epoxy resins and of vapour phase reactions with epichlorohydrin.

SOCIAL DEVELOPMENT THROUGH FAMILY AND HOME

THE report of the conference on "Social Development through the Family and Home," which was held at St. Hugh's College, Oxford, during September 7–25, 1959, under the auspices of the Secretary of State for the Colonies, has now been published (Pp. ii+94. (London: H.M. Stationery Office, 1960.) 4*s*. net).

The conference, the third in a series dealing with social development in Britain's overseas territories, was attended by representatives of 28 territories and by participants from four international organizations, from the Colonial Office and from the Secretary of State's Advisory Committee on Social Development.

The report directs special attention to the role of the family as a basic unit of society, and to the need for Governments to adopt a social development policy to support it in conditions of rapid social and economic change. It recommends the establishment, in overseas territories, of 'ministries of social development,' supported by departments or services with trained workers, and the setting up of social development councils to advise Governments. Among its recommendations on the training of social service workers, the report points out the need, in rapidly changing societies, for trained workers. Their training should for preference take place in the territories in which they will work, although it recognizes the advantage of some additional training overseas for occupants of the highest posts.

More specifically, the report recommends the introduction into schools of education for family life, so that both boys and girls may learn to play a happy and considerate part as young people and later as adults in the circle of their families and friends. Informal education among adults "is one of the most important ways of establishing a right relation between formal schooling and social development".

Turning to food, nutrition and health, the report advocates the study of dietary habits, consumer education, and community development campaigns to improve health and hygiene. Recognizing the importance of housing, it calls for advance consideration of the needs and customs of those who will live in houses which are being planned. Against the background of economic development, facilities for employment of women, the establishment of day nurseries, industrial welfare, social security and recreational facilities are considered to assume increasing importance. The report describes as important the availability of advice to families and as urgent the need for study of the legal status of the family, with particular reference to the new patterns of family life emerging as a result of industrialization and the growth of towns.

LABORATORY-TEACHING OF LANGUAGES

WITH the aid of mechanical and electronic devices, students may now use entire class periods for practice in reading, speaking and comprehension during language laboratory sessions (Industrial Bulletin of Arthur D. Little, Inc., No. 373; March 1960).

The language laboratory system emphasizes the 'hearing and speaking' approach which is endorsed by the Modern Languages Association of the United States and the American Council of Learned Societies. The students are exposed to their new material on an essentially private basis. In general, comprehension, performance and speed of learning are greatly improved under the new system.

The Federal Government has recognized the need of language laboratories by providing support for the new facilities, as well as sponsoring scientific research on the mechanics of language teaching. Many colleges, high schools and even private industrial firms have installed language laboratories, where students attend at least once a week. Eventually such laboratories may become so widespread that college entrance requirements in language will include oral as well as written tests.

In class, students sit in semi-sound-proof isolation booths provided with earphones; a master tape-recording is played, and the teacher may project slides or other visual aids simultaneously. Master tapes may be pre-recorded and catalogued and filed like library books; special text-books and exercises accompany each tape. Well-placed pauses in the tape allow the student to repeat phrases; the whole class is monitored by the teacher, who may tune in to make corrections of inflexion and pronunciation. Special instruction may be given to individuals needing it most, thus solving in part the familiar class-room problem of dividing teaching time equally among students.

Language laboratories are not intended to replace teachers, but to supplement them. Although, under the new system, students can progress faster than under the old, and will have more opportunity to develop their conversational abilities, the teacher will still be needed to explain linguistic structure, to correct errors, and to prepare good master tapes.

IONOSPHERIC MODIFICATION OF THE RADIO EMISSION FROM JUPITER

By PROF. ALEX G. SMITH, T. D. CARR, H. BOLLHAGEN, N. CHATTERTON and F. SIX

Department of Physics, University of Florida, and Maipu Radioastronomical Observatory, University of Chile

THE sporadic long-wave-length radio-frequency energy emitted by the planet Jupiter is received in the form of brief pulses, the majority of which range from about 0·2 to 1·5 sec. in duration. Occasionally the radiation is very intermittent, with pulses occurring singly, or at most in twos or threes. However, it is more common for the energy to be received in complex bursts of pulses, with each burst lasting from a few seconds to a minute or more.

An experiment reported in 1958 by Gardner and Shain[1] has thrown considerable doubt on the real origin of these details, suggesting that many of the features may originate in the terrestrial ionosphere. In this experiment, antennæ spaced 25 km. apart were used for simultaneous reception of outbursts from Jupiter, and the received signals were compared by means of high-speed pen recordings. Although only one completely satisfactory pair of records was obtained, it seemed to demonstrate clearly that there were important differences in the signals received at the two sites.

We have recently repeated this experiment, using a much longer base-line. One antenna was located at the University of Florida Radio Observatory, lat. 29° 39′ N., long. 82° 21′ W., while the other antenna was at the Maipu Radioastronomical Observa-

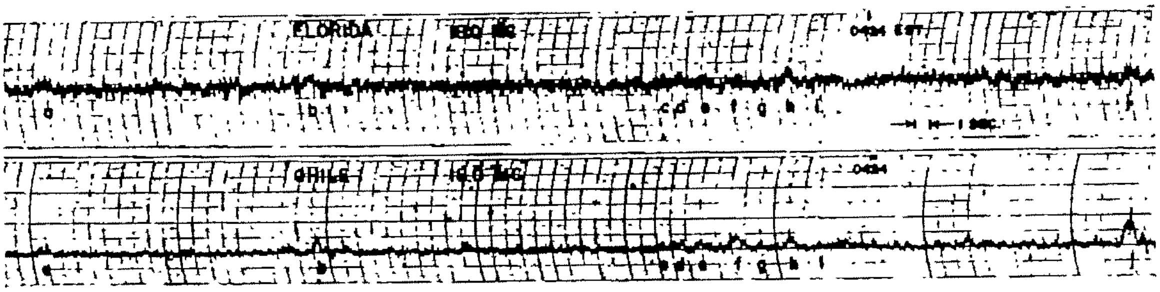

Fig. 1. Period of good correlation from the records of March 29, 1960. Approximate time 4h. 24m. a.m. Eastern Standard Time

tory of the University of Chile, lat. 33° 30′ S., long. 70° 52′ W. The separation of these sites is 7,040 km. Identical receivers were employed at the two Observatories, both receivers being crystal-controlled at 18.000 mc./sec. to eliminate the possibility that differences in the records might be caused by spectral features of the radiation. The recorders were Brush high-speed mechanical oscillographs, having response times of the order of 0·02 sec.; they were operated at a paper speed of 5 mm./sec., which experience has shown is adequate to resolve the details of the pulses.

Simultaneous records of good quality, showing extensive Jupiter activity, were obtained on three nights in early 1960. On March 23 the records overlapped for 31 min., on March 24 for 51 min., and on March 29 for 77 min. Table 1 gives the circumstances of the observations. Time indications were put on all records, either by direct recording of the *WWV* time broadcasts, or by means of a chronometer calibrated against *WWV*; it is believed that the timing was reliable to ± 1/2 sec. Examination of these records immediately confirms the existence of striking differences in the signals at the two sites. While limited sections of the records show fair correlation of the individual pulses, other sections differ so radically that by actual test it proved to be impossible to correlate the records unambiguously without reference to the time marks. In Fig. 1 is shown a period of moderate activity which is rather typical of a number of intervals during which the pulse-to-pulse correlation was reasonably good. To facilitate comparison, the more obvious correlations have been indicated by means of letters. Fig. 2 shows a short section of the records in which the correlation is much poorer. Particularly interesting is the single pulse *a*, which seems to be replaced in the lower record by a series of five or six peaks.

Careful study shows that many of the grosser differences in the records can be explained as the result of alternate fading or scintillation at the two stations; and by comparing the records during times of sustained activity of Jupiter it is even possible to estimate the period of scintillation for each site. In Fig. 3 is shown a typical example of alternate fading at the two locales. Table 2 shows the mean scintillation period for each station for each of the three nights. It will be seen that on these occasions, at least, there were no significant differences in the periods at the two Observatories.

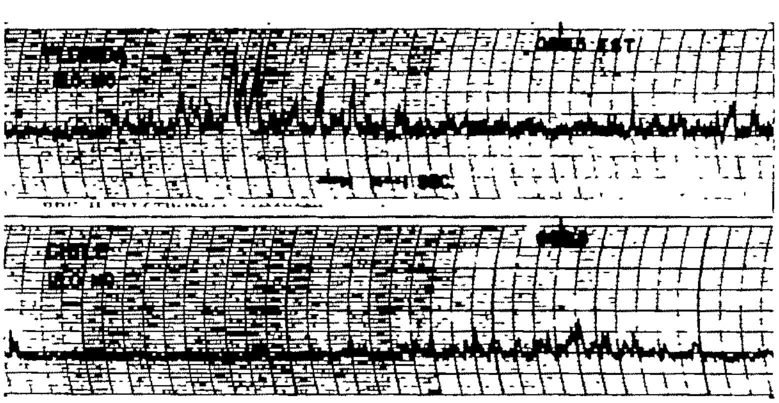

Fig. 3. Out-of-phase scintillations from the records of March 23, 1960. Approximate time 6h. 19m. a.m. Eastern Standard Time

A number of workers have studied the scintillation of radio stars, which is generally attributed to drifting irregularities in the ionosphere[2]. The periods reported range from about 8 sec. to 2 min. and are apparently independent of the wave-length at which the observations are made. These workers have also shown that the scintillation amplitudes increase at the lower radio-frequencies, and for sources of small angular extent. Thus, there is every reason to suppose that the observed Jupiter scintillations are of this type. The more rapid scintillations occurring on March 29 may well be associated with the fact that the geomagnetic activity index *K* was larger on that date than on the two preceding dates, since the radio star observations also indicate that the scintillation frequency increases with *K*.

Although portions of the records can be explained as a simple amplitude modulation of the pulse heights, due to ordinary scintillation, other sections seem to

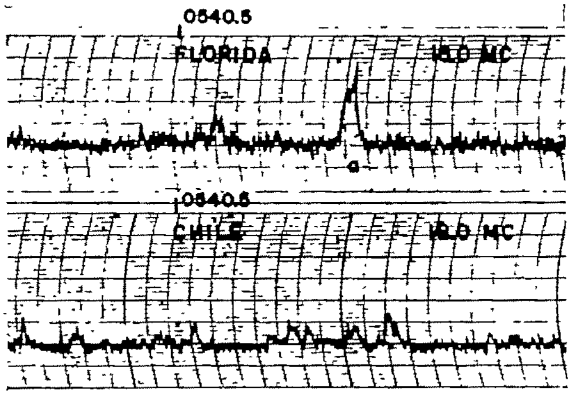

Fig. 2. Period of poor correlation from the records of March 24, 1960. Approximate time 5h. 40m. a.m. Eastern Standard Time

Table 1. CIRCUMSTANCES OF THE OBSERVATIONS

Date	Period of observation (E.S.T.)	Range of altitudes of the planet	
		Florida Station	Chilean Station
Mar. 23	6h. 06m.–6h. 37m. (a.m.)	36°–37°	78°–74°
Mar. 24	3h. 58m.–5h. 48m. (a.m.)	25°–36°	64°–80°
Mar. 29	3h. 40m.–4h. 59m. (a.m.)	25°–33°	64°–77°

Table 2. SCINTILLATION PERIODS FOR THE TWO SITES

Date	Mean scintillation period	
	Florida Station	Chilean Station
Mar. 23	45 sec.	41 sec.
Mar. 24	39 sec.	43 sec.
Mar. 29	28 sec.	29 sec.

show more complex effects. Even where the scintillations are temporarily in phase at the two stations, the individual pulse shapes are frequently distorted beyond recognition, suggesting the presence of a very rapid scintillation component, with a period comparable to the durations of the pulses themselves, superimposed on the slower modulation described above. This effect seems to be present in Fig. 2, and also in the curious distortion of pulse *b* in Fig. 1.

Measurements of the polarization of the sporadic Jupiter radiation received in the northern hemisphere have been reported by Franklin and Burke[3] and by two of us[4]. Southern hemisphere measurements were made by Gardner and Shain[1]. As the latter remark, it is encouraging that all the measurements have indicated right-hand circular or elliptical polarization, since if the effect were terrestrial in origin the sense of the polarization should be reversed in the two (magnetic) hemispheres. Because the previous experiments were not simultaneous, however, some question has remained as to possible influences of the terrestrial ionosphere.

On March 24, March 29, and April 12 of the current year, we obtained simultaneous polarimeter records at a frequency of 22·2 mc./sec. at the Gainesville and Maipu Observatories, the magnetic latitudes of which are + 41° and − 22°, respectively. Because of an undetected partial malfunction of the Gainesville instrument, a quantitative analysis of the records for the axial ratios of the polarization ellipses is probably unreliable. Qualitatively, however, all the records appear to show right-hand circular or elliptical polarization.

In summary, it appears likely that the basic pulse, of the order of duration of 1 sec., originates from Jupiter, since there are periods of good correlation when nearly identical pulses are received at stations 7,040 km. apart. On the other hand, there is evidence that these pulses frequently are seriously distorted by a rapid scintillation component of terrestrial origin, so that individual pulse shapes must be interpreted with caution in these circumstances. Much of the 'burstiness' of the Jupiter radiation—that is, the tendency of the signals to appear as short trains of pulses—seems to be due to a slower terrestrial scintillation component, which in the present experiments had a period of some 30–40 sec. This latter scintillation is probably identical with that commonly observed for the radio stars. The terrestrial ionosphere does not seem to exert any gross influence on the polarization of the Jupiter radiation, since similar polarizations are observed simultaneously in magnetically opposite hemispheres.

This programme has been supported by the National Science Foundation, the U.S. Army Office of Ordnance Research, and the Office of Naval Research. We are greatly indebted to Dr. Federico Rutllant, director of the National Astronomical Observatory of the University of Chile, without whose assistance the establishment of the Maipu station would have been impossible.

SYNERGISM OF BIVALENT METAL IONS IN TRANSPHOSPHORYLATION

By Dr. JOHN M. LOWENSTEIN

Graduate Department of Biochemistry, Brandeis University, Waltham 54, Massachusetts

ENZYME catalysed transphosphorylations to and from nucleoside polyphosphates constitute many of the key reactions of intermediary metabolism. Most or all reactions of this kind show an absolute requirement for bivalent metal ions, which is commonly met by the ions of magnesium, calcium and manganese. The metal ion specificity of such a reaction may be absolute or relative. In either case, inactive metals may act as competitive inhibitors. Moreover, in the case of relative specificity, the presence of two different, active metal ions may lead to an additive effect, or to an effect which reflects the average of each metal ion taken separately. Finally, the possibility exists that the presence of two different metal ions may lead to a superadditive effect. That the interplay of different bivalent metal ions may be of physiological importance is borne out by a consideration of the concentrations of some metal ions in rat liver. These are magnesium, 9; calcium, 3; and manganese, 0·03 µatoms per gram of fresh tissue[1–3].

Non-enzymic transphosphorylations from adenosine triphosphate to a variety of acceptors also show a requirement for bivalent metal ions[4,5]. The non-enzymic reaction dependent on bivalent metal ions:

$$\text{adenosine triphosphate} + \text{orthophosphate} \xrightarrow{\text{metal}^{2+}} \text{adenosine diphosphate} + \text{pyrophosphate}$$

serves as a model for enzyme catalysed reactions involving nucleoside triphosphates, and provides a chemical basis for the bivalent metal ion requirement of enzyme catalysed transphosphorylations. This reaction proceeds readily in the presence of ions such

Table 1. SYNERGISM OF BIVALENT METALS IN TRANSPHOSPHORYLATION

The reaction mixtures contained 5 μmoles [^{32}P]-orthophosphate (2·0 × 10^4 counts/min.); 50 μmoles of sodium adenosine triphosphate, pH 9; 50 μmoles of diethanolamine–hydrochloric acid buffer, pH 9·0; and bivalent metal chlorides as indicated. The final volume was 1·0 ml., temp. 38°, and time of incubation 2 hr. Analyses were performed as described previously (ref. 4)

as calcium, cadmium and manganese, and much more slowly in the presence of ions such as magnesium, beryllium and nickel[4]. Here, too, there exists the possibility that one type of bivalent metal ion may act as a competitive reactant or inhibitor with respect to another type of bivalent metal ion. These possibilities have been studied experimentally using the non-enzymic reaction quoted above. The use together of certain pairs of bivalent metal ions, of which one possesses little or no activity when tested alone and the other possesses high activity when tested alone, leads neither to competitive inhibition nor to an effect which reflects the average of each metal ion taken separately. Instead there can be observed a striking superadditive effect. Results obtained with various combinations of calcium, manganese and magnesium ions are shown in Table 1. In experiment *a* the effects of manganese and magnesium ions were tested separately and together. The first two lines of experiment *a* show that 20 m*M* manganese and 25 m*M* magnesium are insufficient to satisfy the bivalent metal ion requirement of the reaction in the presence of 50 m*M* adenosine triphosphate, and no pyrophosphate is formed. (The symbol m*M* (millimolar), is used to express the concentrations of ions as well as molecules. The terms 'milli-equivalents' and 'milli-ions' are avoided since they may lead to confusion when used for bivalent metal ions in the present context.) However, when these concentrations of manganese and magnesium ions are added together (line 3) they lead to the formation of 71 mμmoles of pyrophosphate. Lines 4 and 5 are controls which show that 103 mμmoles of pyrophosphate are formed in the presence of 45 m*M* manganese, and 4 mμmoles of pyrophosphate are formed in the presence of 45 m*M* magnesium. A concentration of 45 m*M* was chosen for the controls because this was the sum of the concentrations of manganese and magnesium when these were used in combination. It is clear from these results that some, but not all, of the active manganese ions can be replaced by the much less active magnesium ions without loss of activity per μmole of the remaining manganese ions (cf. last column of Table 1). The two metals can therefore be said to work in synergism. The results obtained with calcium and magnesium ions (experiment *b*), and with calcium and manganese ions (experiment *c*) are similar. The synergism is most pronounced when the ion which possesses relatively low activity is present in a concentration which is equal to one-half or more of the concentration of adenosine triphosphate.

Under conditions of pH and adenosine triphosphate/bivalent metal ratio which are suitable for studying the catalytic activity of calcium, manganese and magnesium ions, others, such as barium and strontium ions, give precipitates. The observations reported in Table 1 show that very small concentrations of highly active ions, such as calcium, can be demonstrated to possess catalytic activity in the transphosphorylation reaction if relatively large amounts of, say, magnesium ions are also present. It is therefore possible to test very low concentrations of barium and strontium ions for activity by taking advantage of the sparing action of magnesium ions. The results of such an experiment (Table 2) show clearly that barium and strontium ions can also be classified as highly active in the catalysis of the transfer reaction. This finding could not have been anticipated from previous results[4], which tended to indicate that metal ions active in the non-enzymic reaction have an ionic radius between 0·8 and 1·0 Å.

A bivalent metal ion which possesses little or no catalytic activity on its own can also be classified according to its ability to participate in a synergistic partnership with a highly active metal ion such as calcium. An experiment designed to demonstrate this is shown in Table 3. The ions are listed in descending order of effectiveness as determined by the difference between the activities observed in the presence and absence of calcium ions. The results indicate that some metal ions are very efficient in synergistic partnership with calcium ions, even though they have virtually no activity on their own. Other metal ions are much less effective, whether tested in the presence or absence of calcium ions. An examination of the results obtained with the first four of the metal ions listed in Table 3 also shows that the effectiveness of a metal ion in the synergistic reaction is not directly related to its effectiveness when it is used alone. Thus the increase in the rate of transphosphorylation when calcium ions are added to manganese ions is of the same order as that which is observed when calcium ions are added to magnesium ions. Yet when tested alone, the effectiveness of manganese is much greater than that of magnesium ions. The same considerations apply to a comparison of cadmium and cobalt ions.

The results of Tables 2 and 3 may be summarized as follows: the alkaline earth ions calcium, strontium

Table 2. ACTIVITY OF SOME BIVALENT METAL IONS IN THE PRESENCE OF 40 m*M* MAGNESIUM IONS

The complete reaction mixture contained 5 μmoles diethanolamine [^{32}P]-orthophosphate, pH 9·0 (2·76 × 10^6 counts/min.); 50 μmoles of diethanolamine adenosine triphosphate, pH 9·0; 40 μmoles of magnesium chloride; and 5 μmoles of a second bivalent metal salt as indicated. The total volume was 1·0 ml., temp. 38°, and time of incubation 2 hr.

$NiCl_2$	0	1	0

and barium are highly active in catalysing the transphosphorylation reaction. The ions manganese and cadmium are of moderate activity alone, but are of high synergistic activity. The ions magnesium and cobalt are of very low activity alone, but are of high synergistic activity. Lastly, the ions zinc, copper, iron, mercury and nickel possess very low activity alone, and are of low synergistic activity. Beryllium, which possesses very low activity alone (Table 2 and ref. 4) is probably also of low synergistic activity.

The results presented here demonstrate that the catalytic effect of certain pairs of metal ions is neither the average of the effects observed with each metal independently, nor is it additive. Instead, the effect is superadditive. An attempt will now be made to account for this synergism in terms of the existence of various bivalent metal chelates of adenosine triphosphate.

The postulate that in the active chelate, adenosine triphosphate : bivalent metal ion are as 1 : 1. It is postulated that the chelates adenosine triphosphate–Mg^{2-} and adenosine triphosphate–Ca^{2-} (stability constants K_1) are active in the transphosphorylation reaction, the former possessing a low and the latter a high activity. It is further postulated that the chelates adenosine triphosphate–magnesium–adenosine triphosphate^{6-} and adenosine triphosphate–calcium–adenosine triphosphate^{6-} (stability constants K_2) are inactive in the reaction. These postulates are identical with those which were made to account for variations in the rate of the reaction which are observed on varying the adenosine triphosphate/bivalent metal ratio[4]. If the reaction mixture contains adenosine triphosphate and calcium ions such that the ratio of adenosine triphosphate/$Ca^{2+} > 2$, and if K_2 for Ca^{2+} is sufficiently great, then the main species in the solution will be the inactive chelate adenosine triphosphate – Ca – adenosine triphosphate^{6-}, and the minor species will be the active chelate adenosine triphosphate–Ca^{2+}. If, on the other hand, the solution contains adenosine triphosphate and magnesium ions such that the ratio of adenosine triphosphate/$Mg^{2+} \sim 1$, then provided K_2 for Mg^{2+} is not much bigger than K_1, the solution will contain the low-activity chelate adenosine triphosphate–Mg^{2-} and possibly some of the inactive chelate adenosine triphosphate–Mg–adenosine triphosphate^{6-}. Now if magnesium ions are added to a solution containing adenosine triphosphate/$Ca^{2+} \gg 2$, a shift will occur from the inactive adenosine triphosphate–Ca–adenosine triphosphate^{6-} to the highly active adenosine triphosphate–Ca^{2-} and the low activity adenosine triphosphate–Mg^{2-} (Fig. 1, line i).

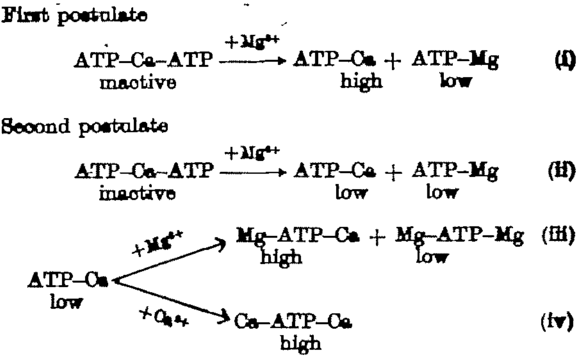

Fig. 1. Various chelates which may be involved in the synergistic effect of two bivalent metal ions on the non-enzymic phosphate transfer from adenosine triphosphate. The word below each chelate refers to the relative rate of phosphate transfer. (Postulate 1 = line i; postulate 2 = lines ii, iii and iv)

The postulate that in the active chelate, adenosine triphosphate : bivalent metal ion are as 1 : 2. It is postulated that the chelates Ca–adenosine triphosphate–Ca and Mg–adenosine triphosphate–Ca are highly active in the transphosphorylation reaction, while the chelates Mg–adenosine triphosphate–Mg, adenosine triphosphate–Mg^{2-} and adenosine triphosphate–Ca^{2-} possess low activity, and those consisting of two molecules of adenosine triphosphate and one bivalent metal ion possess no activity. Suppose that to a solution containing adenosine triphosphate/$Ca^{2+} \gg 2$ there are added magnesium ions, then there will be a shift from the inactive adenosine triphosphate–Ca–adenosine triphosphate^{6-} to the low activity adenosine triphosphate–Ca^{2-} and adenosine triphosphate–Mg^{2-} (Fig. 1, line ii). The addition of further magnesium ions leads to the formation of the high-activity chelate Mg–adenosine triphosphate–Ca and the low-activity chelate Mg–adenosine triphosphate–Mg (Fig. 1, line iii). Addition of calcium ions instead of magnesium ions leads to adenosine triphosphate–Ca^{2-} and thence to the highly active chelate Ca–adenosine triphosphate–Ca (Fig. 1, line iv). The two postulates are not mutually exclusive, and it is possible that both adenosine triphosphate–Ca^{2-} and Ca–adenosine triphosphate–Ca are highly active in the reaction under discussion. Mg–adenosine triphosphate–Ca would then also be highly active.

The results reported here suggest the following hypothesis to account for the differences in the activity of myofibrillar actomyosin adenosine triphosphatase[6,7] in the presence of calcium, magnesium and potassium ions: myosin contains bound bivalent metals[8] (J. Gergely and B. Vallee have found that myosin contains about 1 atom magnesium and 3 atoms calcium per molecular weight of 5 × 10^{5} (personal communication)). It follows that myofibrillar actomyosin adenosine triphosphatase also contains bound bivalent metals. In the absence of added bivalent metal but in the presence of potassium ions there is a slow hydrolysis of adenosine triphosphate which involves the formation of an enzyme–calcium–adenosine triphosphate–potassium complex. At low potassium ion concentrations the rate of hydrolysis of adenosine triphosphate is increased by the addition of magnesium or calcium owing to the formation of enzyme–calcium–adenosine triphosphate–magnesium or enzyme–calcium–adenosine triphosphate–calcium. In the presence of added magnesium the system shows great sensitivity to ethylenediaminetetraacetic acid, because ethylenediaminetetraacetic acid combines preferentially with the bound calcium which is essential for enzyme activity. The formation of enzyme–calcium–adenosine triphosphate–magnesium is prevented by the formation of enzyme–calcium-ethylenediaminetetraacetic acid, and possibly by the subsequent dissociation from the enzyme of some calcium–ethylenediaminetetraacetic acid. In the presence of added calcium the sensitivity of the system to ethylenediaminetetraacetic acid is much lower, and depends in the first instance on the removal of calcium from the solution (and not from the enzyme) by the formation of calcium–ethylenediaminetetraacetic acid. The behaviour of myosin adenosine triphosphatase, although different from myofibrillar adenosine triphosphatase[6], may be accounted for in similar fashion. Myosin adenosine triphosphatase is activated to a much lesser degree by magnesium than is actomyosin adenosine triphosphatase. This reflects a difference in the reactivities of the enzyme–calcium–adenosine triphosphate–magnesium complexes postulated for both hydrolase activities. The postulate is in harmony with the concept that the true substrate of actomyosin adenosine triphosphatase is adenosine triphosphate–calcium or adenosine triphosphate–magnesium, and that free adenosine triphosphate inhibits by being bound to the enzyme without being split rapidly. It does not account for the activation of myosin adenosine triphosphatase which is observed in the presence of ethylenediaminetetraacetic acid under certain conditions[8].

The composite effects of different bivalent metal ions deserve further consideration from the points of view of chelate chemistry and enzyme mechanisms. The importance of such effects in the metabolism of living cells remains to be assessed.

This work was aided by the National Science Foundation and by the Helen Hay Whitney Foundation.

FLUORINE COMPOUNDS IN NATURE; THE DISTRIBUTION OF CARBON-FLUORINE COMPOUNDS IN SOME SPECIES OF *DICHAPETALUM*

By SIR RUDOLPH PETERS, F.R.S., and R. J. HALL

Agricultural Research Council Institute of Animal Physiology, Babraham, and Department of Biochemistry, University of Cambridge

THE presence of an organic compound of fluorine in Nature has been known since Marais[1] isolated fluoroacetic acid from the leaves of *Dichapetalum cymosum*, the South African plant called gifblaar, which is poisonous to cattle; fluoroacetic acid was first synthesized by Swarts[2]. Another plant of the same genus, namely, *Dichapetalum toxicarium*, also called ratsbane, has been known for a long time. It grows in Sierra Leone (West Africa) and is responsible for the condition of 'brokeback'[3], a paralytic state in man. The signs described in animals after eating the seeds of this plant resemble so much those produced by fluoroacetic acid that we examined its seeds for a fluorine compound. Fluoroacetate was present only in traces; but we have now isolated two new fluorine compounds from the seeds of *D. toxicarium*. (1) A fluoro-fatty acid constituting most of the toxic material, which has been finally identified as ω-fluoro-oleic acid[4]. (2) The other, present in much less amount, is a saturated long-chain fatty acid possibly having 17 carbon atoms.

Several problems of botanical and other interest arise from these observations.

The question is whether the difference in fluoro compounds in the seeds of *D. toxicarium* as compared with the leaves of *D. cymosum* is a property of the species or whether it is merely due to the storage of the C_2 acid by conversion in the seeds to long-chain fluoro-fatty acids. This has led us to examine the leaves and seeds of *D. cymosum* for fluoro-oleic acid and other fluorine compounds.

D. cymosum seeds. We are indebted to Dr. R. A. Dyer, chief of the Division of Botany, Department of Agriculture, Pretoria, for sending us some of these seeds, which are stated to be rare, as the plant is difficult to find in fruit.

No trace of fluorine was found in the powdered dried seed after ashing. This proved the absence of any fluoro compound within the sensitivity of the tests. There was not enough material for animal tests to confirm whether these seeds were toxic. It has been stated in the literature that the seeds are toxic so the matter requires further investigation; but it seems evident that any fluoroacetate made is not being metabolized and stored in these seeds as a long-chain acid, as happens in *D. toxicarium*.

D. cymosum leaves. These were examined to see if there was present any long-chain fluoro-fatty acid, and if so, whether it was identical with the material from *D. toxicarium*.

The leaves were finely ground in a Cassell mill, and 100 gm. extracted with light petroleum (boiling range 40–60°). The residue after removing the solvent was saponified with methanolic potassium hydroxide, the saturated long-chain fatty acids were separated from acetone solution at $-20°$ C. and discarded. The acetone solution now contained 0·624 gm. of an oil, mainly of unsaturated acids, and analysis showed that it contained 1·415 mgm. fluorine. When injected into three rats at doses, which in terms of fluorine content would have been toxic as a long-chain fatty acid, no effect was found.

The crude acids were treated according to the recent method given[4] for purifying fluoro-oleic acid. About 20 mgm. of a purified oil was obtained which, when chromatographed by a modification of the

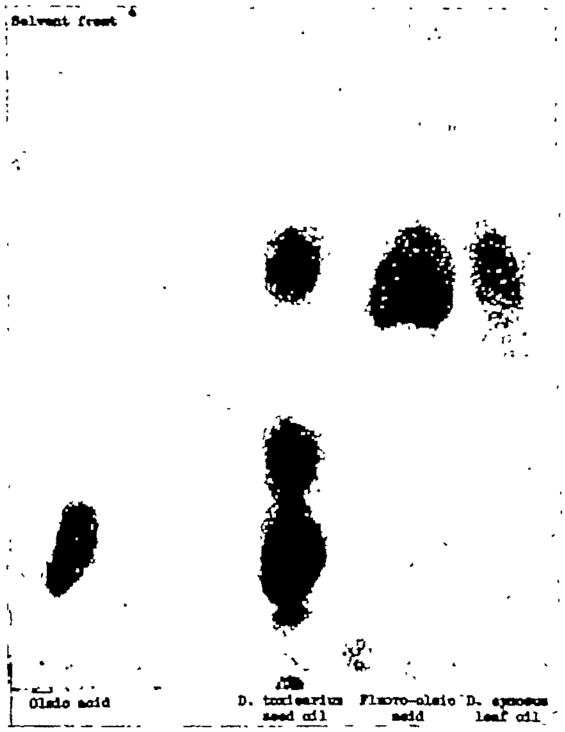

Fig. 1. Ascending chromatogram of unsaturated fatty acids of *Dichapetalum* species, etc., on Whatman No. 531 filter paper impregnated with liquid paraffin, developed with 85 per cent v/v acetic acid/water and demonstrated with iodine vapour

method of Schlenk *et al.*[5], gave the chromatogram shown in Fig. 1. There was present, therefore, a long-chain acid with approximately the same R_F value as fluoro-oleic acid. A long-chain fluoro-fatty acid with an even number of C atoms has a powerful inhibitory effect on citrate metabolism when tested on kidney particle preparations from the guinea pig *in vitro*; 5–10 μgm. of the acid shown to travel as fluoro-oleic acid on the chromatogram was found to inhibit the metabolism of citrate in such preparations. The unknown acid therefore had some of the properties of fluoro-oleic acid, but it differed in that it was not toxic *in vivo* at double the usual fatal dose to rats. The problem requires further exploration; our tentative interpretation is that the leaves of *D. cymosum* can contain in small amounts a long-chain fluoro-fatty acid of 17 or 18 C atoms, which is different from those at present known, though an alternative explanation could be that the crude acids contain a component interfering with toxicity *in vivo*. One batch of *D. cymosum* leaves which we received contained none of this compound. In accordance with previous work by others[6], we have found that the total fluorine content of specimens of leaves varied greatly; from 63 to 270 μgm. fluorine per gm. of dried leaves.

D. toxicarium leaves. When these were ground and extracted in the manner as were the leaves of *D. cymosum*, no fluorine was detected on ashing and no trace of a long-chain fluoro-fatty acid.

From the preceding observations it can be concluded that the presence of fluoro-oleic acids in the seeds of *D. toxicarium* is a property of the seeds of this species and not of the seeds of the genus in general. Furthermore, the leaves of this species cannot contain much fluoroacetic acid (Table 1) as no fluorine was found on ashing. There is a distinct indication that there are still more fluorine compounds to be discovered in *D. cymosum* leaves, though it seems unlikely that the toxicity is due to such compounds, which would be present only in traces compared with fluoroacetic acid.

The question also arose whether leaves from a plant of *D. cymosum* grown in England would also contain large amounts of fluorine. Some seeds were kindly brought back from Johannesburg five years ago by Sir Edward Salisbury, who arranged for these to be grown by Mr. Stenning, at the Royal Botanic Gardens, Kew. Two leaves were taken from a plant about 12 in. in height, and were analysed for fluoride after combustion, using a micro-diffusion technique[7]. Relatively large amounts of fluorine were present, 112 μgm./gm. This is in the range of our other figures for total fluorine, and that of the 150 μgm./gm. recorded by Marais[1]. These amounts are to be compared with those of grasses generally, 9–26 μgm./gm. and alfalfa 15–36 μgm./gm.[8]. These authors noted that the fluorine increased as the plants grew and the season advanced; lawn grass was found to contain 16 μgm./gm. dried grass in May and 53 μgm. fluorine/gm. in November. Specimens of tea may give higher values; for example, we found 150 μgm./gm. in a sample of Indian tea.

Other Dichapetalum species. During the course of our work, we have been able to examine leaves and stems and roots from several other African species. The scientific interest was reinforced by the possibility that the ingestion of some might account for unexplained deaths of cattle in East Africa. The plants examined have been the following:

Belgian Congo: (1) *D. flabellatiflorum*, Hauman., origin, Germain 0594; (2) *D. thonneri*, de Wild, origin, Louis 6712; (3) *D. thonneri*, de Wild, origin, Louis 13016. East Africa: (4) *D. ruhlandii*, East Africa; (5) *D. mossambicense*, Engl.; (6) *D. stuhlmanii*, Engl.

Tests were made of toxicity to rats mainly by dosing orally. The material was finely ground and administered with rat cake, a method which demonstrates well the toxicity of *D. toxicarium* seeds. None of the plants tested with doses up to about 2·0 gm. proved toxic to the extent of killing the animal. In two cases with *D. stuhlmanii* a temporary depression of the heart-rate was observed. On killing the animals some hours later the citrate contents of the hearts were 326 and 141 μgm./gm. wet tissue and in the kidneys 553 μgm./gm. and 73 μgm./gm. wet tissue respectively, which is to be compared with a normal value of 40 μgm./gm. ± 10.

Table 1. FLUORINE COMPOUNDS IN LEAVES AND SEEDS OF *D. cymosum* AND *D. toxicarium*

0 = not measurable.

* Or long-chain fluoro-fatty acid

† Extracted at *p*H 1·0.

‡ After hydrolysis with conc. sodium hydroxide, represent fluoroacetate and any other alkali labile CF compounds.

As a further control the residues from light petroleum extracts, equivalent to 20 gm. of the leaves of (4) and (5), were injected in acetone into rats; they were non-toxic and without effect upon the citrate content of heart, liver or kidney. This proved the virtual absence of toxic long-chain fluoro-fatty acids.

Since some of these plants have been described as toxic in the literature and presuming their toxicity is due to fluorine compounds, we conclude that the toxicity varies as it does in *D. cymosum* and possibly that the specimens collected for us were harvested at the less-toxic period.

Some of our results are summarized in Table 1.

In addition to those mentioned, we are indebted to Prof. Z. M. Bacq, Dr. M. F. Jurion, director-general, Institut national pour l'Etude agronomique du Congo Belge, and others for help in collecting the plants from the Belgian Congo, to Dr. Galley and staff of the Tropical Products Institute, London, for helping in collecting the West African specimens; to Dr. Greenway for East African plants, and to South African colleagues for specimens of *D. cymosum* leaves. We are also grateful to Miss R. Shawdon and to D. Harbidge for skilful technical assistance with part of the work, and to Prof. F. G. Young for facilities provided.

SUSTAINED ACTION OF INJECTED CHELATING AGENTS

By Dr. A. LINDENBAUM and Dr. J. SCHUBERT

Division of Biological and Medical Research, Argonne National Laboratory, Lemont, Illinois

It is noteworthy that, following a single injection of an appropriate chelating agent in subjects whose tissues contain foreign radioactive or non-radioactive metals such as plutonium, thorium, or lead, the subsequent urinary excretion of the metal usually remains well above the control levels for days and even weeks. Since most of the chelating agent administered is rapidly eliminated from the body, this is an unexpected phenomenon which merits investigation. For example, within 6 hr. after injection into rats, about 94–98 per cent of ethylenediaminetetraacetic acid and diethylenetriaminepentaacetic acid is excreted, and at the end of 24 hr. most of the retained dose is in the gastrointestinal tract, with smaller amounts generally diffused throughout the tissue[1]. A very small fraction of the injected dose of the pentaacetic acid persists in the blood for several days[1].

Evidence has been adduced[2] to indicate that these chelating agents combine with the metal to form diffusible chelates within the tissues (though not necessarily intracellular). It is reasonable to assume that the sustained excretion of plutonium after treatment with diethylenetriaminepentaacetic acid[3] reflects the slow but steady diffusion of the metal chelate from the tissues into the blood-stream and thence into the urine. We have made a direct test of this assumption in experimental animals by measurement of the ultrafilterability of the tissue deposits of different radioisotopes following treatment with chelating agents. Ultrafiltration techniques have been useful in determining the state of radioelements in solution[4]. They offer a simple, rapid and effective means for screening potential chelating agents for the treatment of radioelement poisoning, as shown here and elsewhere[5].

Low-pressure ultrafiltration techniques were used[4]. In earlier work described in Fig. 2, suitable pressure was applied by a water pump using 150 mm. mercury pressure. In all other experiments ultrafiltrates were obtained by centrifugation at about 900*g* in a modification of the method of McFarland and Hein[6]. It was possible with the latter technique to obtain 0·1–0·5 ml. of filtrate after centrifugation of a 2–5 gm. sample for 15–45 min. In order to minimize the uncertainties resulting from uneven deposition of colloidal particles due to hydrolysis of plutonium and thorium, we have studied the ultrafilterability of the radioisotopes from blood and tissues taken from intravenously injected animals rather than by *in vitro* addition of the radioisotope to tissue samples. In some cases the chelating agents were added *in vitro* to the tissues of animals previously injected with the radioisotope but not treated with the chelating agents. In other cases, ultrafilterability of the radioisotopes was measured from tissues of treated animals.

In preparation for ultrafiltration, rat bone (the entire weighed calvarium) was fragmented with scissors and crushed in a glass homogenizer with the aid of 5 ml. added saline. The entire weighed liver was either similarly homogenized or was simply cut into small pieces before being placed without saline in Visking bags. The radioactivity of the ultrafiltrate was determined in duplicate or triplicate. The values obtained after treatment with, or addition of, chelating agent were corrected for dilution differences and compared with those from ultrafiltrates of appropriate control tissues.

The effects of diethylenetriaminepentaacetic acid on excretion of plutonium are of interest. The calcium salt (335 mgm./kgm. body-weight as the acid form) or saline was given intraperitoneally to rats three days after a single intravenous injection of a solution containing 35 μgm. plutonium-239 in 1 per cent sodium citrate at *p*H 5–6. The rats and their saline controls were killed at intervals of 1, 2, 3 and 7 days after injection. The ultrafilterability of plutonium from the bone, liver, and plasma was measured directly (see Fig. 1). It is evident that plutonium deposited in the tissues has been rendered diffusible by the pentaacetic acid and that the diffusibility remains ten or more times greater than that of the control animals for at least 7 days after a single injection of plutonium.

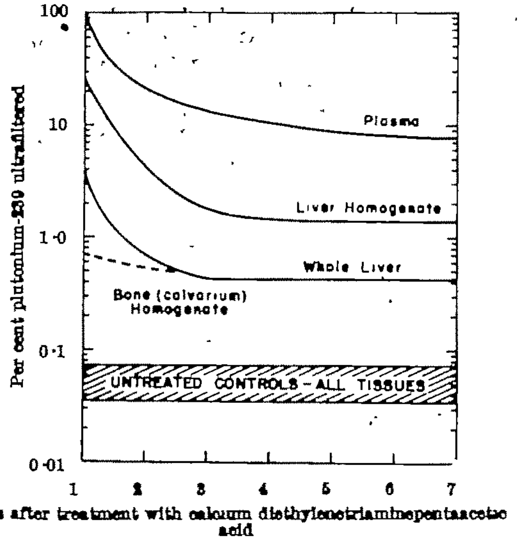

Fig. 1. Ultrafilterability of plutonium-239 from tissues of rats injected intraperitoneally with calcium diethylenetriaminepentaacetic acid (235 mgm./kgm. body-weight as the acid form) three days following intravenous injection of 35 μgm. plutonium-239

The effectiveness of diethylenetriaminepentaacetic acid relative to ethylenediaminetetraacetic acid in promoting the ultrafilterability of plutonium was tested using plasma and heparinized whole blood. The plutonium was injected intravenously into rats, and 2 ml. of blood was withdrawn 15 min. later. Solutions of the chelating agents were added to the whole blood or to the plasma to provide final concentrations ranging from 10^{-8} to 10^{-4} M. The superiority of diethylenetriaminepentaacetic acid over ethylenediaminetetraacetic acid is shown by the sharper rise in the plutonium content of the ultrafiltrates at concentrations of chelating agent in the range 10^{-6} M–10^{-4} M (Fig. 2).

It has been previously pointed out[7] that as a result of the mass-action equilibrium, the presence of calcium ions in blood prevents any appreciable chelation of strontium ions. Consequently, ethylenediaminetetraacetic acid and related chelating agents, in the usual therapeutic doses, are useless for treatment of radiostrontium poisoning. In ultrafiltration experiments, the lack of interaction of strontium with ethylenediaminetetraacetic acid was shown directly by adding strontium-85 and known amounts of the calcium salt of the latter to rat plasma. At concentrations of ethylenediaminetetraacetic acid as high as 10^{-3} M the ultrafilterability of the strontium-85 was unchanged from that of the controls (75 per cent compared with 74 per cent), as could be predicted from the mass-action equations[7]. At a concentration of 2×10^{-2} M ethylenediaminetetraacetic acid—a blood concentration unattainable in living animals—there was an increase in the amount of ultrafilterable strontium.

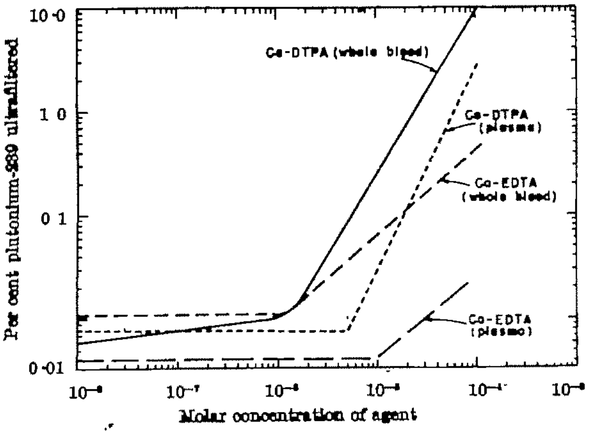

Fig. 2. Effect of concentration of chelating agent on ultrafilterability of plutonium-239 in blood. Plutonium was injected intravenously; chelating agent was added *in vitro*

Experiments similar to those described above for plutonium were made with thorium using thorium-234 as tracer. The ultrafilterability of thorium from plasma and tissues obtained from rats injected intravenously with thorium-234 was measured in the presence of 10^{-4} M chelating agent added *in vitro*. The marked superiority of diethylenetriaminepentaacetic acid relative to ethylenediaminetetraacetic acid and other chelating agents is shown in Table 1. A similar superiority of the former over the latter in accelerating the excretion of thorium from animals has also been demonstrated[8]. Such results confirm what could be anticipated by comparison of the constants[9] for formation of the 1 : 1 chelates (log K(Th-EDTA) = 23·2; log K(Th-DTPA) = > 27),

Table 1. EFFECT OF CHELATING AGENTS ADDED *in vitro* ON THE ULTRAFILTERABILITY OF THORIUM-234 FROM RAT TISSUES

Chelating agent (calcium salt)	Thorium-234 content ultrafiltered (per cent)		
	Plasma	Liver	Bone
Saline controls	0·26	1·2	0
Ethylenediaminetetraacetic acid	2·3	—	—
1 : 2-*Bis*-[2-di (carboxymethyl) aminoethoxy] ethane	3·9	—	—
2 : 2′-*Bis* [di (carboxymethyl) amino] diethyl ether	4·2	—	—
Diethylenetriaminepentaacetic acid	26	85	~10

The plasma and tissues were obtained from rats killed 15 min. after injection of a carrier-free solution of thorium-234 in 1 per cent sodium citrate at pH 5. The chelating agent was added to give a final concentration of 10^{-4} M.

It should be mentioned that, unlike the situation with radioactive metal poisons, where maximum elimination is a necessary goal, an effective therapeutic agent need not increase the ultrafilterability of a non-radioactive metal poison, and may in fact decrease it. A case in point is acute beryllium poisoning, in which successful treatment has been shown to involve inactivation of beryllium without necessarily increasing its excretion or diffusibility[10].

This work was carried out under the auspices of the U.S. Atomic Energy Commission.

SAP-TRANSMISSIBLE VIRUSES ASSOCIATED WITH DISEASES OF GRAPE VINES IN EUROPE AND NORTH AMERICA

By C. H. CADMAN
Scottish Horticultural Research Institute, Invergowrie, by Dundee

H. F. DIAS* and B. D. HARRISON
Rothamsted Experimental Station, Harpenden, Hertfordshire

DEGENERATION of the grape vine has been recognized as a major factor in viticulture since the nineteenth century and has been attributed to many causes, ranging from unfavourable soil conditions to bacteria, fungi and viruses[1]. In Europe, three main groups of diseases have been transmitted by grafting and therefore ascribed to viruses[2]: (*a*) court-noué, Reisigkrankheit, urticado; (*b*) panachure, Panaschüre, clorose infecciosa; (*c*) enroulement, Rollkrankheit. Recently, Ochs[3] has claimed to have transmitted potato viruses *X* and *Y* and cucumber mosaic virus to herbaceous plants by inoculation of sap from grape plants affected by diseases of types (*a*) and (*b*). However, later work failed to confirm Ochs's results[4].

Virus diseases which appear similar to those in Europe also occur in Californian vineyards, and two of these diseases, fanleaf and yellow mosaic (similar to groups (*a*) and (*b*), respectively), are contracted from soil[5,6]. The virus that causes fanleaf disease is transmitted by a soil-inhabiting dagger nematode, *Xiphinema index* Thorne and Allen[7].

Grape vines are little grown in Britain; but three groups of soil-borne viruses have been reported in other crops[8], and members of each group also occur in Continental Europe[9–11]. All these viruses are readily transmitted by inoculation of sap to a wide range of herbaceous species, and one of them, *Arabis* mosaic virus, has a dagger nematode (*Xiphinema diversicaudatum* Micoletzky) as a vector[12,13]. We now report the transmission of viruses from grape vines to herbaceous hosts and describe some properties of the viruses. Our results show that viruses isolated either from North American or from European grape vines have similar properties to *Arabis* mosaic (= raspberry yellow dwarf) virus, and that they have some of their antigens in common with it.

Isolation of Viruses from European and North American Grape Vines

Sap from vine leaves seems to contain little or no tannin but has a pH value of about 3·5. Young grape leaves were therefore macerated in 0·07 *M* phosphate buffer at pH 8·0 or in 2·5 per cent nicotine solution, in an attempt to raise the pH value of the sap, and hence to lessen both virus inactivation and damage to inoculated leaves of test plants. 'Celite' abrasive powder was added to all inocula. Using this method, viruses were transmitted from diseased vines obtained from four different countries to *Chenopodium amaranticolor* Coste and Reyn., tobacco (*Nicotiana tabacum* L. var. White Burley), *N. clevelandii* Gray, cucumber (*Cucumis sativus* L.) and French bean (*Phaseolus vulgaris* L. var. Prince). No transmissions were obtained from normal plants of several of the same vine varieties (Table 1). The symptoms in *C. amaranticolor*, which resemble those caused by *Arabis* mosaic virus[14], are chlorotic lesions in the inoculated leaves and systemic symptoms, which start in the young leaves as chlorotic vein-banding or mottling; later, the whole plant is stunted and the leaves deformed. Different isolates from vine vary greatly in virulence, and systemic symptoms in *C. amaranticolor* take 7–20 days to appear, whereas those caused by *Arabis* mosaic virus usually take only 5–10 days.

In the other species symptoms also develop more slowly than with *Arabis* mosaic virus. All the vine isolates caused chlorotic or necrotic local lesions in inoculated leaves of tobacco and systemic mottling or necrotic ringspot symptoms in *N. clevelandii*. The Portuguese urticado *A*, Swiss court-noué and North American fanleaf *A* isolates produced systemic yellow blotching in cucumber, and chlorotic local lesions in inoculated leaves of French bean together with systemic mottling. Portuguese urticado *B*, Portuguese clorose infecciosa, French court-noué and North

* Calouste Gulbenkian Foundation Research Fellow from the Estação Agronomica Nacional, Portugal.

American fanleaf *B* isolates were less virulent than these three. Least virulent were French panachure and Swiss panachure isolates: these caused chlorotic local lesions in inoculated cucumber cotyledons but did not become systemic. They did not infect French bean, and they caused much milder symptoms in tobacco, *N. clevelandii*, and *C. amaranticolor* than those caused by the first group of isolates.

Many of the isolates (for example, Portuguese) came from grape plants that were infected by grafting, with ungrafted grape plants of the same clone serving as control material. The plants generously supplied from California by Dr. W. B. Hewitt, however, included six plants of *Vitis rupestris* var. St. George, each of which had become infected with vine fanleaf virus when exposed to infective *Xiphinema index*, and six normal St. George plants of the same clone. Virus was transmitted to *C. amaranticolor* and *N. clevelandii* from five fanleaf-infected plants (the sixth died) but from none of the normal ones, indicating that the isolates are consistently associated with fanleaf disease and are transmissible by *X. index*.

Properties of the Viruses

Table 2 shows that the five isolates selected for more detailed study have broadly similar stabilities *in vitro*. The differences seem to result from the greater concentration in sap attained by the more virulent isolates.

Portuguese urticado *A* and Portuguese clorose infecciosa are examples of isolates that have similar effects on herbaceous plants and have similar properties *in vitro*, but yet come from grape plants that show very different types of symptoms: such isolates should not, therefore, be assumed to be strains of the same virus. However, they are sufficiently closely related for the presence of one to affect the other[15]. Thus, *C. amaranticolor* inoculated simultaneously with both isolates showed symptoms intermediate between those shown by plants infected with only one or other of the isolates. Similar interactions were observed between the Portuguese urticado *A* and a North American nematode-transmitted (fanleaf *B*) isolate.

Electron microscopy of partially purified preparations (made from *C. amaranticolor* by a butanol/chloroform method[16]) of the Portuguese urticado *A*, Portuguese clorose infecciosa and North American nematode-transmitted (fanleaf *B*) isolates showed that all three contain many spherical particles of diameter approximately 30 mμ (Fig. 1). No such particles occurred in preparations made by the same method from healthy *C. amaranticolor* plants.

Sap from *C. amaranticolor* plants infected with the vine isolates did not precipitate specifically with antisera to tomato black ring or raspberry ringspot viruses, two soil-borne viruses from Britain that have many properties in common with the vine viruses. By contrast, tests with antisera to *Arabis* mosaic virus and to North American fanleaf *A* isolate showed that these two viruses have some of their antigens in common (Table 3). All the French and Swiss isolates also precipitated specifically with both antisera, but at lower antiserum titres than the homologous viruses. There seems no possibility that the grape vine isolates were mixtures of *Arabis* mosaic and some other virus, for none of them infected *Petunia hybrida* plants systemically, a reaction characteristic of *Arabis* mosaic virus. Moreover, *C. amaranticolor* plants systemically infected with North American fanleaf *A*, Portuguese urticado, Swiss court-noué and French panachure isolates are susceptible to infection with *Arabis* mosaic virus. This is further evidence that the vine isolates and *Arabis* mosaic virus are only distantly related strains of the same virus.

Association of *Xiphinema index* with Urticado Disease in Portuguese Vineyards

Although several workers have obtained evidence that vine viruses are contracted from the soil in Europe[17], and fanleaf virus is transmitted by *X. index* in California[7], the identity of the vectors in Europe is uncertain. In Portugal, urticado disease often occurs patchily in vineyards, and examination of soil samples from two different vineyards showed that the distribution of urticado coincides with that of a nematode probably identical with *X. index*, whereas another species of *Xiphinema*, *X. americanum* Cobb, occurred in soil from all parts of the vineyards. The

ecology of the virus causing urticado and other similar European vine diseases may thus be similar to that of vine fanleaf virus in California.

Conclusions

Although it is not yet certain that the vine viruses can be transmitted to herbaceous plants so readily that this method can be used for routine diagnosis of virus infection in grape vines, its application on an experimental scale provides a new approach to the study of the relationship between the viruses associated with grape vine diseases, particularly those in the following two groups: (1) fanleaf, Reisigkrankheit, urticado, court-noué, and (2) yellow mosaic, clorose infecciosa, Panaschure and panachure. Our results show that similar viruses can be isolated from plants with each of these diseases, regardless of the group to which the diseases belong, but not from normal plants. However, vines with 'yellow mosaic' may perhaps also contain avirulent strains of fanleaf virus, because 'fanleaf' is usually common in vineyards where 'yellow mosaic' occurs: thus, the isolates obtained from grape vines with 'yellow mosaic' may not be the cause of the yellow mosaic symptoms. We have transmitted North American fanleaf *A* isolate back to grape vine by grafting to infected *Chenopodium amaranticolor*, but to what extent the other viruses we have transmitted to herbaceous plants are responsible for the vine diseases with which they are associated must remain uncertain until further tests have been made. The results of the serological tests indicate that the sap-transmissible isolates from grape vines, and *Arabis* mosaic virus, are all strains of one virus, but they also suggest there are considerable antigenic differences between isolates. Further work is in progress to find whether these differences reflect vector specificity or geographical variation, or both.

We are much indebted to Dr. W. B. Hewitt, Davis, California; Dr. R. Bovey, Nyon, Switzerland; and Mr. A. Vuittenez, Colmar, France, for supplying normal and infected grape vines; to D. J. Hooper for identifying the nematode species, and to H. L. Nixon, J. Cathro and R. D. Woods for examining preparations with the electron microscope.

POLYPLOIDY IN HUMAN TUMOURS

By N. B. ATKIN and ANGELA J. ROSS

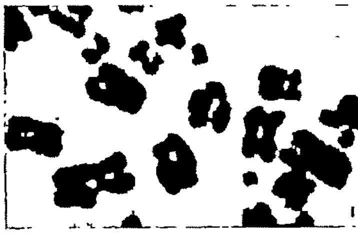
Department of Cancer Research, Mount Vernon Hospital, Northwood, Middlesex

MALIGNANT tumours, like normal tissues, exhibit varying degrees of polyploidy, but whereas in normal somatic tissues the great majority of cells usually retain the diploid chromosome complement, malignant tumours often have a pronounced secondary complement of polyploid cells, or may have undergone a shift to a basically near-tetraploid chromosome number. Although primary tumours may have an apparently normal chromosome complement, aneuploidy is a common finding and moreover is the rule in animal tumours which have been transplanted for a long time[1]; in the mouse, the change to aneuploidy often appears to involve a doubling of the chromosome complement, since many of the tumours have near-tetraploid chromosome numbers. The significance of polyploidy in the evolution of transplantable mouse tumours has been discussed by Levan[2,3], who has demonstrated that near-tetraploid tumours show much more evidence of structural chromosomal change than do near-diploid tumours. It is uncertain, however, to what extent the findings in experimental animal tumours have their parallel in human malignant disease.

We wish to present some evidence relating to the occurrence of polyploidy in human tumours. We have now accumulated data on the chromosome complement and deoxyribonucleic acid content of malignant tumours from a variety of different sites. Whereas extensive chromosome counts have been made on only a few suitable tumours, microspectrophotometric estimations of deoxyribonucleic acid, not being similarly restricted by technical considerations, have been performed on a large number of tumours[4-6]. We have already noted[4] that, although individual tumours extend over a wide range, they tend to fall into two groups as regards their modal deoxyribonucleic acid value, which are centred in the hyperdiploid and tetraploid regions respectively. This has been confirmed by a further study on 165 uterine tumours[5], in which the deoxyribonucleic acid data have been considered in relation to the histological and clinical features of the tumours. In this work it was found that the cervical carcinomata (132 cases) fell into two approximately equal groups; the majority of corpus tumours however, fell into the hyperdiploid group. If the modal deoxyribonucleic acid value, derived from measurements on interphase cells, can be taken to be representative of the stem-line of the tumours, it would appear that, in a considerable proportion of cases, the stem-line chromosome complement of the tumour has doubled at some stage of its evolution.

It is of interest that published data on the chromosome numbers of human tumours do not appear to show a similar bimodal distribution[7-9]. This might be because there has been a selection of those tumours that prove most suitable for chromosome counting: near-triploid tumours may have been selected because they more frequently provide countable prometaphases or metaphases in squash preparations than do those having higher numbers. Another possible reason for the discrepancy is a lack of parallelism that we have found in some tumours between deoxyribonucleic acid content and chromosome number: in a series of 14 tumours[10] we found on an average a significantly higher ratio of modal deoxyribonucleic acid content to chromosome number than for the homologous normal cells, and it appeared that this difference was on the whole greater for those tumours with high chromosome numbers. Thus a nearly triploid tumour might have a modal deoxyribonucleic acid content which would correspond to a hypotetraploid chromosome number if the average amount of deoxyribonucleic acid per chromosome were the same as that in the normal diploid cells. Perhaps chromosomal doubling is commonly followed by structural changes and loss of chromosomal material, resulting in a reduction in the number of chromosomes and an increase in their average size.

It is of course possible that some of the tumours that are 'tetraploid' as regards modal deoxyribonucleic acid content are polytene and not polyploid, but we have so far obtained no direct evidence for the occurrence of polyteny in human tumours. It is also possible that the presence of a large component of cells which have synthesized deoxyribonucleic acid prior to mitosis might result in a tumour with a near-diploid stem-line chromosome number having an interphase population that is mainly 'tetraploid' as regards deoxyribonucleic acid content, as was in fact described for an ovarian carcinoma by Bader[11]. However, chromosome counts of greater or lesser accuracy on most of our 'tetraploid' tumours have been in keeping with the deoxyribonucleic acid data. Moreover, with a few exceptions (see below), the tetraploid tumours do not retain any cells having diploid amounts of deoxyribonucleic acid, and where measurements of deoxyribonucleic acid have been made on cells in mitosis, these have been consistent with a near-tetraploid rather than a near-diploid chromosome number.



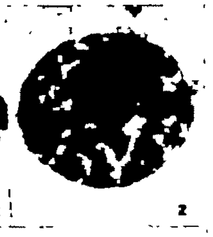


Fig. 1. Endoreduplication: diplochromosomes at metaphase (carcinoma of the corpus uteri). (× 2700)

Fig. 2. Endomitosis (carcinoma of the cervix uteri). (× 1320)
Acetic orcein squash preparations

Our results are derived from patients at the time that they enter hospital for treatment, and it is not known at what stage the doubling of the chromosome complement has occurred in the near-tetraploid tumours. Evidence is forthcoming, however, from cytological studies that polyploidization is occurring in some of these tumours. The work of Biesele, Poyner and Painter[12] and of Levan and Hauschka[13] has demonstrated the part played by endomitosis and endoreduplication in the growth of experimental tumours of the mouse. In human tumours, we have likewise noted these two phenomena; but whereas endoreduplication, as revealed by the presence of diplochromosomes in succeeding mitoses, has been found occasionally in a number of tumours, we have noted that certain tumours are characterized by a high frequency of cells exhibiting chromosomal contraction and splitting within the nuclear membrane, corresponding to the classical picture of endomitosis[14]. The highest incidence of endomitosis was seen in certain undifferentiated squamous cell carcinomata and adenoacanthomata of the cervix uteri. In general, endomitosis was a fairly frequent phenomenon in squamous cell tumours, but was only rarely seen in adenocarcinomata. The deoxyribonucleic acid data derived from tumours showing a high frequency of endomitosis are of interest: the modal deoxyribonucleic acid value fell most often in the hypertetraploid region, but several tumours also had a smaller secondary hyperdiploid mode; a few of the tumours had a hyperdiploid primary mode and a prominent secondary hypertetraploid mode. These tumours may be in a state of equilibrium; alternatively, they may be in the process of transition from a hyperdiploid to a hypertetraploid state. It was noted that endomitosis was not a feature of tumours which had a hypotetraploid deoxyribonucleic acid mode.

The question arises as to whether the incidence of endomitosis and endoreduplication in a particular tumour is an unchanging feature of the tumour, or whether it is dependent on environmental influences, for example, varying hormonal levels. In Levan and Hauschka's[13] work on mouse tumours, each tumour was characterized by a particular level of endomitosis or endoreduplication. In certain normal tissues, however, there is evidence that hormonal factors may determine the occurrence of polyploidy. Thus Arias-Stella[15] has demonstrated the association of nuclear hypertrophy in endometrium with retained chorionic tissue. He has suggested that the atypical pattern results from hormonal activity of the chorionic tissue, and also quotes instances of nuclear enlargement in other tissues which may be the result of endocrine activity. The occurrence of polyploidy in human[16] and mouse[17] liver may be dependent on anterior pituitary growth hormone. So far as the human cervical tumours are concerned, no clear evidence for a hormonal or other 'host' factor has come to light, but an apparent difference in age-distribution between tumours with different deoxyribonucleic acid modes is perhaps suggestive of a hormonal influence: it was noted[5] that the age-distribution of those tumours with high modal deoxyribonucleic acid values was flatter, with relatively fewer cases in the middle age-groups, than that of the near-diploid tumours, and 11 cases aged over 74 had tetraploid modes, as compared with one which was diploid. These differences, however, are not statistically significant. On the other hand, when we calculate the relative height of the secondary (tetraploid) mode in 25 near-diploid squamous cell cervical tumours chosen at random, we find that in 9 cases more than 20 per cent of the cells fall within ±15 per cent of the secondary mode, and of these 7 were from patients aged over 54. Only 5 of the 16 tumours with smaller secondary modes were from patients aged over 54. This difference is just significant ($p = 0.033$). A similar calculation for 18 near-tetraploid tumours shows that 6 out of 8 occurring in patients aged over 54 have prominent secondary octoploid modes, as compared with 4 out of 10 in younger patients. The presence of a prominent secondary mode at twice the value of the primary mode does not necessarily imply that there are many cells with a doubled chromosome complement; but there is no evidence that other factors, such as the frequency of cells entering mitosis, are responsible for the observed differences, which may therefore reflect the incidence of endomitosis or other doubling processes.

It was found[5] that the modal deoxyribonucleic acid value of nearly a third of the squamous cell tumours of the cervix fell within ± 15 per cent of the normal diploid value. Most of these tumours had only small or moderate secondary 'tetraploid' modes. The tumours showing endomitosis, however, frequently had modes (primary and secondary) which were at least 15 per cent higher than the corresponding normal diploid or tetraploid values. It is hoped that further work now being undertaken will shed some light on the significance of this difference and on other problems connected with the occurrence of endomitosis and related phenomena in human tumours. As to the relation between polyploidy and the degree of differentiation of the tumours, we have noted that there appears to be a correlation in the case of tumours of the corpus uteri, well-differentiated tumours being mainly near-diploid; no such correlation has, however, been found for squamous cell carcinomas of the cervix, or for squamous cell tumours arising at other sites.

In summary, human tumours frequently have a primary modal deoxyribonucleic acid value in the tetraploid region, suggesting that chromosomal doubling has occurred in the majority of, or all, the cells. Further, cytological observations suggest that endomitosis or some other doubling mechanism may play a part in the growth of human tumours, endomitosis in particular being a prominent feature of some tumours, which usually have hypertetraploid modes. There is evidence to suggest that the incidence of polyploidy in carcinoma of the cervix may bear a relation to the age of the patient.

Thanks are due to Dr. Alma Howard and Dr. L. H. Gray for helpful discussion; also to Mr. G. Lee for technical assistance. This investigation has been supported by a grant from the British Empire Cancer Campaign.

THE ANTARCTIC CONVERGENCE—AND DIVERGENCE

By Dr. K. WYRTKI

Division of Fisheries and Oceanography, Commonwealth Scientific and Industrial Research Organization, Cronulla, Sydney

IN a recent paper, Wexler[1] gives observational evidence of prevailing divergent motion along the line which is usually called the Antarctic Convergence. Mackintosh[2] has determined the position of this line from surface-temperature data, considering the strong temperature gradient at the boundary of the antarctic and the sub-antarctic surface waters as indicative of its position. But until now no observational evidence has been given for convergent motion along this line, as the sinking of the antarctic intermediate water occurs usually a few degrees farther to the north, as can be seen from the salinity sections given by Deacon[3].

Considering the Antarctic Convergence as a surface phenomenon in the light of Ekman's theory, it is evident that divergent motions connected with upwelling must occur to the south of the maximal westerlies and convergent motions and sinking to the north of them, but such a transverse circulation would not lead to the formation of a distinguishable water mass boundary. Consequently, this boundary must be related to the dynamics of the antarctic circumpolar current. Stommel[4] has sketched a Sverdrup-type solution for the circumpolar current, in which the wind stress is balanced by a zonal pressure gradient, caused by the boundary formed by South America. This model explains the southward shift of the current; but it implies that the current is situated completely to the south of the maximal westerlies.

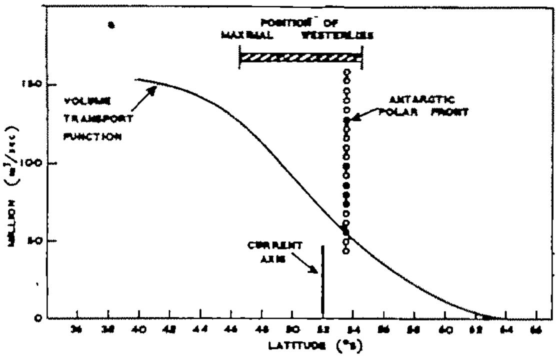

Fig. 1 Average positions of the belt of maximal westerlies of the antarctic polar front and volume transport function of the antarctic circumpolar current

In order to check the relative positions of the belt of maximal westerlies, the circumpolar current and the Antarctic Convergence, their average positions have been determined. In Fig. 1 the position of the belt of maximal westerlies according to Wexler[1], that of the Antarctic Convergence according to Mackintosh[2] and the volume transport function relative to the antarctic continent according to Kort[5] are given. This diagram shows clearly that the axis of the circumpolar current coincides almost with the maximal westerlies and that the Antarctic Convergence lies just to the south of this position. Consequently the circumpolar current cannot be explained exclusively by a Sverdrup-type solution; but friction must also be of importance, and its effect will be to make the current coincide with the west wind belt. In fact, in Wexler's diagram, this belt shows a shift to the south, corresponding to that of the circumpolar current.

A frictional conception of the circumpolar current allows an explanation of the water mass boundary, usually called the Antarctic Convergence. In the presence of friction the motion is no longer geostrophic, but has a down-slope component. If friction is considered to be proportional to the velocity, the angle α between the velocity vector and the isobars is given by $\tan \alpha = \frac{r}{f}$, where f is the Coriolis parameter and r the friction coefficient. With $f = 10^{-4}$ sec.$^{-1}$ and $r = 2\ 10^{-6}$ sec.$^{-1}$, $\tan \alpha$ is 1/50 and $\alpha = 1{\cdot}2°$, which is indeed a small angle.

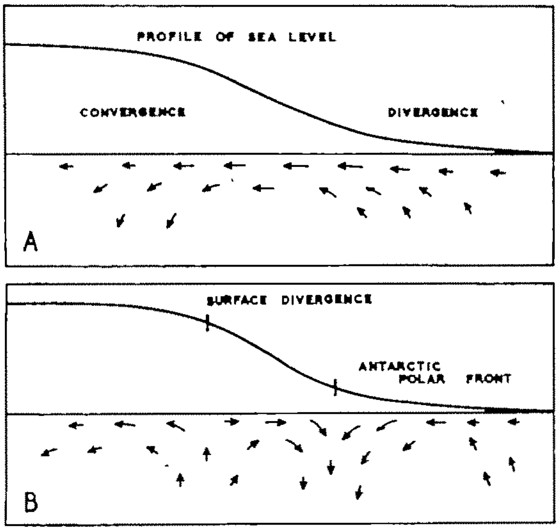

Fig. 2. Schematic representation of the topography of sea-level and of the transverse circulation in the surface layer of the antarctic circumpolar current at (A) strong west winds, and (B) weak west winds

The meridional motion at the surface near the centre of the current is now the result of the combined effects of the northward component of the Ekman drift current and of the down-slope motion due to friction, caused by the meridional pressure gradient. The north component of the velocity v_E of the Ekman drift current is $v_E = \frac{\pi\,\tau}{\delta D f}$, where τ is the zonal wind stress and D the depth of the Ekman layer. With $\tau = 0{\cdot}8g$ cm.$^{-1}$ sec.$^{-2}$, $D = 100$ m., $\delta = 1g$ cm.$^{-3}$, $v_E = 2{\cdot}5$ cm./sec. results, representing the north component of the drift current under average wind conditions. The down-slope component of the gradient current, on the other hand, is given by $v_g = \frac{1}{r}\frac{\partial h}{\partial y}$, where $\frac{\partial h}{\partial y}$ is the meridional slope of the sea-level. Across the current axis a slope of 50 cm. within 100 km. is quite a likely value, and at the above given value of r, a velocity of $2{\cdot}5$ cm./sec. would result in a southward direction.

With these estimates of the meridional components of the motion near the centre of the current, we can now discuss the effect of strong and of weak winds on the transverse circulation in the current. At strong west winds ($\tau > 0{\cdot}8$) the surface flow is divergent to the south of the maximal westerlies, a northward transport of surface waters occurs across the current axis, because the velocity of the drift current exceeds the down-slope velocity, and convergent motion occurs to the north of the maximal westerlies. This pattern of the transverse circulation is sketched in Fig. 2A and is almost identical with the conception of Wexler[1] of divergent and ascending motion just to the south of the maximal westerlies. At weak west winds ($\tau < 0{\cdot}8$) the down-slope flow in the centre of the current exceeds the drift current, causing a convergence at the right flank of the main current and a sinking motion, which intensify the water mass boundary there. The circulation pattern (Fig. 2B) shows, moreover, a divergence to the north of the maximal westerlies, which appears clearly in charts of surface currents[6].

A diagram giving G.E.K. vectors along a section across the circumpolar current, taken by a Russian ship[7] along 20° E., shows clearly that the meridional components of the motion are southwards between 49° and 51° S., where the temperature diagram indicates the Antarctic Convergence, and northwards to the north as well as to the south of this belt.

From this discussion it must follow that the 'Antarctic Convergence' is a divergence at strong west winds, and a convergence at weak west winds, but as it is always a water mass boundary and a clearly distinguishable feature in the antarctic waters, it is suggested that it be named the 'Antarctic Polar Front'. This does not specify the character of vertical movements along this line and is in accordance with the terminology used for the corresponding feature in the northern hemisphere.

LETTERS TO THE EDITORS

COSMOLOGY

Interpretation of Cosmology

Prof. W. H. McCrea's views on the interpretation of cosmology[1] call for some comment. If the universe turns out to have an inhomogeneous character, then his remarks may be justified. But, in view of the paucity of observational tests that have been adequately investigated so far, it would seem that he takes up a prematurely pessimistic position.

McCrea asserts that there is an uncertainty of knowledge of the factors affecting the physical conditions in those remote parts of the universe which we now see at an early stage in their history, due to the finite velocity of light. This uncertainty, he claims, increases with the observed red shift, and he is led to suggest that differences between various cosmological models cannot be detected as a matter of principle. In particular, calculated distinctions between a steady-state universe and an evolving universe may be meaningless.

There is, of course, uncertainty about the factors affecting any set of phenomena, until we put forward a definite theory accounting for them. For this purpose it may even be necessary to introduce factors or agents that we cannot ourselves observe, if we have reason for believing that they must be observable to other observers whose past experience has been similar to our own. This is in accordance with accepted scientific method. We must try to fit the facts to what seems the most likely interpretation.

In the case of the cosmological problem the simplest and most direct approach, suggested by the Hubble law and the nebular counts, is to assume the 'cosmological principle'. This leads to a definite set of cosmological models: one is the steady-state model and the rest are evolutionary.

As I have shown in recent papers[2,3] there are several tests which, given a plausible continuation of present advances in astronomical technique, should definitely decide whether the universe is in a steady state or not. It is true, as McCrea points out, that the steady-state predictions differ from those of the evolutionary cases only in terms of order z, where z is the red shift. But on the other hand, the predictions for a steady-state model are quite definite and must be realized in a steady-state universe on a statistical basis, if we always choose fair samples for our observational data. There is no uncertainty in principle about the conditions prevailing in remote regions of a steady-state universe, since they must be the same conditions that we experience in our own 'neighbourhood' at the present moment. Consistent agreement of the universe with the various features predicted by all possible tests for the steady-state model must therefore establish it, scientifically, as the correct fit. Consistent disagreement, in ways that cannot be explained by observational errors, must eliminate it.

If the universe is found to be not in a steady state then, retaining the cosmological principle, we must next regard it as evolving in a systematic way. In this case there are indeed great difficulties in predicting exactly what we should see in remote regions in the various models, because of the uncertain degree of evolution that has taken place during the 'light time'. However, it should be appreciated that, by the cosmological principle, the conditions viewed right up to our observational horizon were realized in our own neighbourhood at the same cosmic epochs in the past. It is not inconceivable, therefore, that we may ultimately find an adequate description of these phenomena in agreement with our own discovered past. Such a possibility should not be excluded as a matter of principle.

The difficulties of interpretation which arise in an evolutionary universe were of course pointed out by the original advocates of the steady-state model[4]. Even greater difficulties arise if we drop the cosmological principle and assume, say, a hierarchical model of the universe. In this case the uncertainty of the universe *in toto* would indeed be of the fundamental character that McCrea has envisaged.

An observational decision in favour of a steady-state, evolutionary, or hierarchical universe would have an importance not confined to physics. In due time it would find its place in the basic philosophical outlook of all mankind. Every possible effort should therefore be made to reach it.

[4] Bondi, H., and Gold, T., *Mon. Not. Roy. Astro. Soc.*, 108, 252 (1948).

Dr. Davidson re-states the orthodox view, and it is this view that I venture to call in question.

Suppose we know all about the laws of interaction of different parts of the universe, and suppose we make all the observations of the universe that are possible to us in principle. Then, for the reasons that I stated, I conclude that there is an uncertainty about what we can predict about the universe. The orthodox view is that theory can enable us to overcome this uncertainty. The view I suggested is that we cannot do better than in the circumstances just supposed, and that therefore theory ought to be modified so that it does not claim to do better.

The uncertainty contemplated here is of a more novel and fundamental kind than appears to be altogether recognized in Dr. Davidson's discussion. Also, there is nothing necessarily pessimistic about it. If we could properly take account of it, it would be expected to lead to the discovery of new phenomena just as the sacrifices made in going from classical theory to relativity and quantum theory led to the discovery of new phenomena. Finally, there is nothing contrary to the 'accepted scientific method'. For, in regard to what Dr. Davidson has to say on the subject, we have to recall that no amount of agreement with observation can 'establish' a theory; all that such agreement means is the absence of what we deem to be a contradiction.

PHYSICS

Diamagnetic Moment of Gaseous Plasmas measured by Spin Resonance Techniques

WE report here typical experimental results obtained in measuring the diamagnetic moment of plasmas immersed in static or quasi-static magnetic fields. Nuclear and electron spin resonance techniques were used for detection of magnetic field shifts; the results indicate that such techniques may be of value as a diagnostic tool in high-energy plasma research.

A well-known theorem in statistical mechanics by Van Leeuwen[1] states that the magnetic moment of a classical free electron gas in thermodynamic equilibrium in a magnetic field is zero. The physical interpretation of this result is due to N. Bohr[2], who argued that the moment due to the electron Larmor orbits in the volume of a substance is identically cancelled by a boundary current of electrons elastically reflected by its surface.

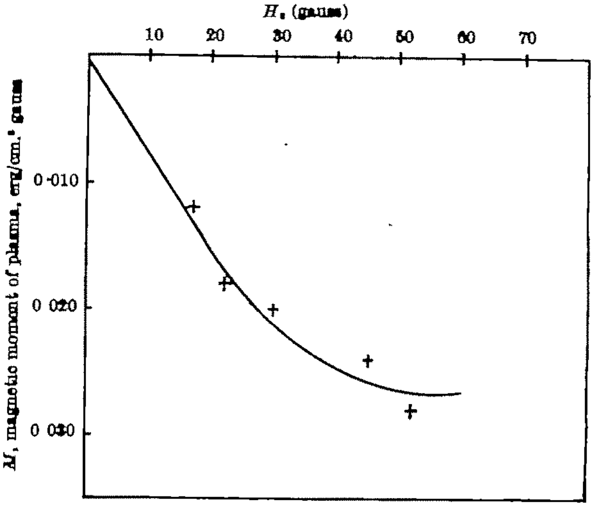
Since Bohr considered the electron gas in a metal, which is degenerate rather than classical, his result appears to be irrelevant. Also, in view of the larger paramagnetic susceptibility of the electron gas in most metals, the diamagnetic moment from the Larmor motion is inaccessible to direct measurement.

A dense free electron gas in a laboratory gaseous plasma is a classical gas which ordinarily is Maxwellian distributed except under special conditions. However, in general it is not in thermodynamic equilibrium; energy and particles are diffusing continuously to the surface or other limiting boundaries. The bounding surface, which provides a region of recombination for electrons and ions in a plasma, is more absorbing than reflecting. It follows that a gaseous plasma immersed in a magnetic field will have a non-zero diamagnetic moment. Using a conventional model for ambipolar diffusion in a plasma, Alfven[3] showed that the moment of the plasma should be:

$$M = -\frac{nk(T_e + T_i)}{H_0} \frac{1}{1 + \frac{\nu_e \nu_i}{\omega_{He}\omega_{Hi}} + \frac{\nu_e^2}{\omega_{He}^2} + \ldots} \qquad (1)$$

where n is the number density of charges, T_e and T_i are the electronic and ionic temperatures, ω_{He}, ω_{Hi} are the electronic and ionic cyclotron frequencies, and ν_e, ν_i are the collision frequencies for momentum transfer of the electrons and ions. For our work at low pressures and degrees of ionization (less than 3 per cent) and relatively high electron temperatures (greater than 10^4 deg. K.), the momentum transfer collisions are determined by the elastic and inelastic cross-sections of the neutral molecules. M is a maximum for $\nu_e\nu_i = \omega_{He}\omega_{Hi}$.

To measure the functional form of M for low fields, we use an electronic spin resonance in diphenylpicrylhydrazyl[4] to record the small decrease in magnetic field observed just outside the discharge tube on its axis. This is done by placing about 0·1 gm. of diphenylpicrylhydrazyl in a coil which forms one arm of a balanced bridge, fed by a radio-frequency of 40–160 Mc./s. Resonances about 1¼ gauss wide are displayed on an oscilloscope when H_0 is modulated by a periodic signal. If the plasma is pulsed every other period, then the entire resonance is displaced alternately on the oscilloscope, and field shifts as low as 0·1 gauss may be detected. The results of such a study on a low-pressure d.c. mercury discharge are shown in Fig. 1. The moment, which is obviously zero at zero field, appears to reach a maximum near 50 gauss, and from equation 1, one obtains an energy density of 2·8 ergs/cm.³. This agrees within 10 per cent with data on energy density taken by pulsed Langmuir probe techniques[5]. Low-field measurements on M taken many years ago by Steenbeck[6], using different methods, agree with our results.



Mercury discharge, 5μ pressure
j = 0·75 amp./cm.²

Fig. 1. Diamagnetic moment of a mercury plasma

The above method is limited in its applications by (1) poor sensitivity because of the wide resonance line width of diphenylpicrylhydrazyl and (2) because measurements of the shift of the electronic spin resonance must be made in the presence of a noisy plasma.

For measurements at high magnetic field intensities, we have used a 'π/2 pulse' proton resonance technique such as described by Hahn[7] and Spokas and Slichter[8]. A pulse of radio frequency, tuned to the resonance frequency of protons in a glycerine sample in or near a plasma in a Varian electromagnet, nutates the nuclear magnetization 90 degrees into a plane perpendicular to H_0 in a few microseconds. The radio-frequency excitation is removed from the sample, and the frequency of precession of the nuclear spin magnets following the pulse is compared with the frequency of the radio-frequency source; the accumulated phase difference between the two signals provides a measure of the field deviation from resonance. Any

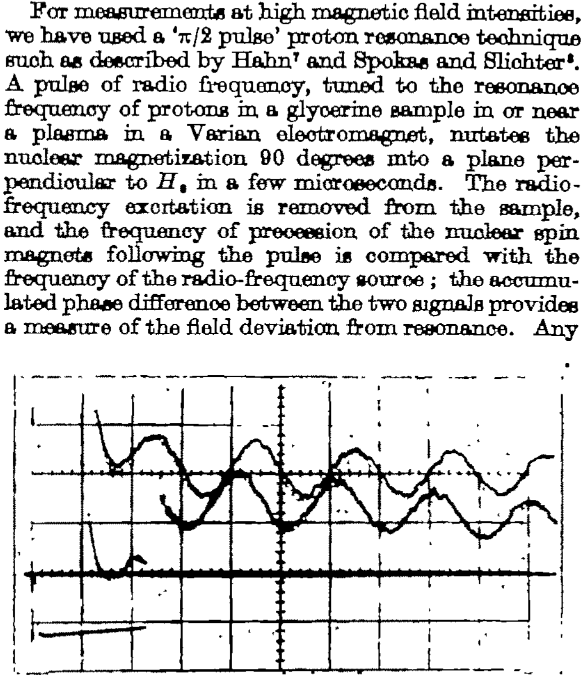


Fig. 2. Upper traces, nuclear magnetic resonance signals for phase comparison; lower trace, discharge tube current. 200 μsec./cm.

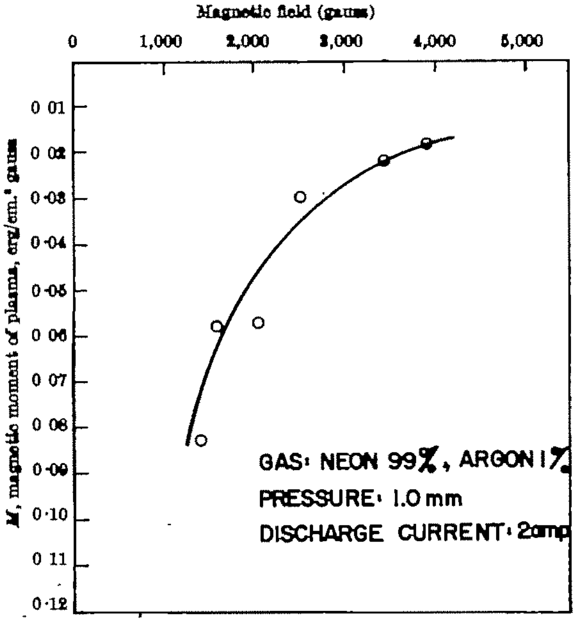

Fig. 3. Diamagnetic moment of a noble gas plasma

field produced by the diamagnetism of the plasma will further alter this deviation.

Fig. 2 shows the signals obtained. The upper damped sinusoid shows the nuclear resonance signal as it is phase detected after removal of the radio-frequency pulse (over-loaded portion far to left). The lower trace shows the same signal, but after a discharge current pulse was applied to a xenon plasma at about 5μ pressure. The discharge tube current, about 6 amp., is displayed as the square pulse at the lower left. The spin precession signals are displaced in phase and in this instance the field shift amounts to 0·12 gauss. The discharge tube here was a modified Phillips ion gauge type[9] which gives a high ionization efficiency in a magnetic field. The energy density is about 50 ergs/cm.³. The phase shift was consistent in sign with the diamagnetism. Stray fields owing to currents passing through the discharge tube were found to give no observable phase shifts of their own. Fig. 3 shows typical results obtained in a relatively strong magnetic field.

The limit of small field detection would appear to be about 1 part in 10⁶, with suitable narrow-banding techniques to improve the signal/noise ratio. Note that these measurements can be made after the plasma discharge, the principal noise source, is over.

An experiment to increase further the electronic energies by cyclotron resonance heating of the electrons at microwave frequencies is now in progress.

The above results imply that spin resonance techniques may be useful in high-energy plasma research and thermonuclear work, for example: (1) Measuring energy densities of plasmas in magnetic fields utilizing plasma diamagnetism as given by equation 1. (2) Measuring any quasi-static magnetic field in a discharge using a small nuclear magnetic resonance probe, which yields $\int B(t)\,dt$ directly.

We gratefully acknowledge the assistance of Prof. C. P. Slichter in giving advice on the nuclear resonance experiment.

Distorted Wave Approximation for Scattering Phase-Shifts

THE elastic scattering wave-function for a short-range potential function $V(r)$ may be written in the form:

$$[\psi_l(r) = kr[j_l(kr)\cos\delta_l - g_l(r)n_l(kr)\sin\delta_l] \qquad (1)$$

where $j_l(x)$ and $n_l(x)$ are the spherical Bessel and Neumann functions respectively, δ_l is the scattering phase-shift, and $g_l(r)$ is a form factor measuring the distortion of the incident wave by the potential. $g_l(r)$ must satisfy the boundary conditions

$$g_l(r \to 0) \sim r^{2l+1},\ g_l(r \to \infty) \to 1$$

We substitute (1) into the integral equation for the phase-shift[1];

$$\sin\delta_l = -(2\mu\hbar^2k)\int_0^\infty V(r)krj_l(kr)\psi_l(r)dr \qquad (2)$$

leading to:

$$\tan\delta_l = B_{1l}/(1 - B_{2l}) \qquad (3)$$

where:

$$B_{1l} = -(2\mu/\hbar^2k)\int_0^\infty V(r)k^2r^2j_l^2(kr)dr \qquad (4)$$

$$B_{2l} = (2\mu/\hbar^2k)\int_0^\infty g_l(r)V(r)k^2r^2j_l(kr)n_l(kr)dr \qquad (5)$$

B_{1l} is the first Born approximation integral and B_{2l} a new integral which is large at low energies, corresponding to strong distortion of the incident wave-function, and small at high energies.

The simplest choice of $g_l(r)$ is made by introducing a cut-off range r_a beyond which the potential tail is negligible:

$$\begin{aligned} g_l(r) &= f_l(r) \qquad (r < r_a) \\ &= 1 \qquad (r > r_a) \end{aligned} \qquad (6)$$

$f_l(r)$ must obey the boundary conditions:

$$f_l(r \to 0) \sim r^{2l+1},\quad f_l(r_a) = 1,\quad f_l'(r_a) = 0 \qquad (7)$$

$g_l(r)$ and $f_l(r)$ are in general series expansions in r. However, $g_l(r)$ is involved only in the integral (5) for B_{2l}, and this has an integrand behaving like r^{2l+2} for small r. Also for $r > r_a$ this integrand is negligible, so that B_{2l} is determined almost entirely by intermediate values of r which are less than r_a. For light nuclei and small and intermediate k values, $f_l(r)$ may be approximated by any monotonically increasing function of r satisfying the constraints (7). To a first approximation, B_{2l} is independent of the detailed shape of $f_l(r)$ as the latter's contribution to the integral is dependent mainly on the second and third conditions (7). Thus B_{2l} is a function of r_a alone to a first approximation.

For non-singular potential wells, B_{2l} is a slowly varying function of r_a, so that r_a may be chosen arbitrarily by inspection of the potential. Singular wells such as the Yukawa potential are somewhat more sensitive to the choice of r_a. In general, best results are obtained if the zero-energy scattering length a is known for the potential $V(r)$. Using the definition:

$$a = \lim_{k\to 0}\left(-\frac{\tan\delta_0}{k}\right) \qquad (8)$$

(3) may be used to find the value of r_a leading to the correct a. Values of r_a obtained by this zero energy normalization procedure are slightly different according to the function used for $f_l(r)$. A simple polynomial expression which is found to give good results for a number of potential shapes is:

$$f_l(r) = \tfrac{1}{2}[(2l+3)(r/r_a)^{2l+1} - (2l+1)(r/r_a)^{2l+3}] \qquad (9)$$

For k large, $B_{2l}/B_{1l} \to 0$ and δ_l is small, so we get a second Born approximation from (3):

$$\delta_l \approx B_{1l}(1 + B_{2l}) \qquad (10)$$

For k small, (3) reduces to the shape-independent formula[2]:

$$k\cot\delta_0 = 1/a + \tfrac{1}{2}r_0k^2 + 0(k^4) \qquad (11)$$

with approximate values of the parameters a and r_0.

A simple illustration of the application of formula (3) for δ_l is given by the ^3S and ^1S scattering of neutrons by protons at low energies, assuming square well potentials. We take for the nuclear well dimensions the following values[3]:

$$^3S: V_0 = 36{\cdot}354 \text{ MeV.}, b = 2{\cdot}0048 \times 10^{-13} \text{ cm.}$$

$$^1S: V_0 = 14{\cdot}052 \text{ MeV.}, b = 2{\cdot}5860 \times 10^{-13} \text{ cm.}$$

where V_0 and b are the depth and range respectively of the potential.

In this case we should take $r_a = b$. Values of δ_0 calculated by the exact formula, by the first Born approximation B_{10}, and by (3) are given in Table 1.

Table 1. CALCULATED VALUES OF PHASE-SHIFTS δ_0 FOR ^3S AND ^1S n–p SCATTERING BY SQUARE WELLS

Spin state	k	Exact δ_0	Born approximation B_{10}	δ_0 from (3)
^3S	0·1	2·6283	0·2337	2·6019
	0·25	2·0590	0·5600	2·0381
	0·5	1·5176	0·9626	1·5319

	0·5	0·9214	0·6979	0·9479

Values of δ_0 are improved by an order of magnitude at all energies over first Born approximation results. Similar results are obtained for other potential shapes with r_a chosen in these cases by the zero energy normalization method above.

For non-singular wells, such as gaussian, exponential or Woods–Saxon interactions, the accuracy of phase-shifts obtained using (3) is better than 2 per cent. Singular wells such as the Yukawa potential may give somewhat less accurate (but still good) results, as the spherical Neumann function $n_l(kr)$ in (1) no longer correctly describes the irregular solution of the wave equation. This actually contains logarithmic terms for a potential with a $1/r$ singularity.

METEOROLOGY

Small-Scale Turbulent Diffusion in the Atmosphere

Frenkiel and Katz[1] have recently published under this title the results of their experiments with instantaneously created smoke puffs. Starting from Taylor's expression for the variance of the mean concentration in such a puff, assuming $R(\alpha)$, the Lagrangian correlation function, to be near unity for small values of the diffusion time, they have derived an expression for the radius of the outer visible boundary of the smoke puff, a, as a function of the diffusion time, t. They arrived at a nearly linear relationship between a and t for small values of t. This conclusion is fully supported by their experimental results.

However, one can doubt the validity of the assumption $R(\alpha) \sim 1$, since the experiments were carried out under conditions of unstable equilibrium of the atmosphere. According to Sutton's arguments[2], or following the more rigorous treatment of Clarenburg[3] for the diffusion of smoke puffs emerging from an instantaneous point source, it seems better to put a proportional to $t^{2-n/2}$, at least for small values of t, where n is a parameter depending on the turbulent state of the atmosphere.

To decide which of the two relations is the better one, we have calculated: (1) $R(a,t)$, the correlation of a as a function of the time and the diffusion time plus 3 sec., thus allowing for the fact that the experiments were not carried out with a perfect point source. (2) $R(a,t^{2-n/2})$, the correlation of a as a function of the time and $(t+3)^{2-n/2}$.

The results obtained are summarized in Table 1. The values of a as a function of the time were taken from the tables published by Frenkiel and Katz.

Table 1

Date	Puff No.	$R(a,t)$	$R(a,t^{2-n/2})$*	$R(a,t)-R(a,t^{2-n/2})$
27/2/1950	4	0·9937	0·9948	− 0·0011
	5	0·9644	0·9670	− 0·0026
	7	0·9442	0·9464	− 0·0022
	8	0·9563	0·9599	− 0·0037
	16	0·9872	0·9862	+ 0·0010
	18	0·9813	0·9894	− 0·0081
	19	0·9642	0·9644	− 0·0002
	20	0·9784	0·9808	− 0·0024
28/2/1950	1a	0·9865	1·0000	− 0·0135
	1b	0·9554	0·9610	− 0·0056
	2a	0·9842	0·9851	− 0·0009
	2b	0·9933	0·9941	− 0·0008
	3	0·9909	0·9899	+ 0·0010
	5	0·9634	0·9668	− 0·0034
	9	0·9841	0·9821	+ 0·0020
	10	0·9650	0·9698	− 0·0048
	11	0·9760	0·9846	− 0·0086

*For n the value 0·26 was taken.

As can be seen from Table 1, both correlations are highly significant. However, $R(a,t^{1-n/2})$ is in nearly all cases somewhat greater than $R(a,t)$. Applying Student's t test to the differences $[R(a,t) - R(a,t^{1-n/2})]$, it appears that $R(a,t^{1-n/2})$ is significantly ($P < 0\cdot5$ per cent) higher than $R(a,t)$.

From the experiments of Frenkiel and Katz it may therefore be concluded that the more complete theory of diffusion yields results which are in better agreement with the experimental data. Because the difference between our treatment and that of Frenkiel and Katz is already clearly demonstrated for unstable atmospheric equilibrium, it must be expected, for reasons the discussion of which would be beyond the scope of this communication, that this difference will be even more pronounced for stability of the atmosphere.

We wish to thank the Board of the National Defence Research Council, T.N.O., for permission to publish this communication.

ENGINEERING

Initiation of Chemical Reactions by Mechanical Forces

It is well known that large molecules can be degraded mechanically, and the rupture of a chemical bond by a high shearing stress under conditions of laminar flow has been demonstrated with a 'jet viscometer'[1]. The free radicals formed on degradation by shear give rise to oxidation and other chemical reactions. Evidence of such an initiation of chemical reactions by mechanical forces was found with lubricating oils which had been used in an internal combustion engine while the engine was run 'cool' (sump temperature: 69·4° C.). A comparison was made of the change in viscosity and the dependence of viscosity on temperature of the oils when, on one hand, the engine was driven by an electric motor and, on the other hand, run on a fuel the lead content of which was varied. It appeared that the lead content of the fuel promoted a breakdown of large molecules and the combination of free radicals with oxygen molecules, which in their turn formed linkages for the growth of splinter molecules.

In all these experiments the viscosity of the oil decreased logarithmically with the time of running the engine, while the temperature coefficient of the viscosity increased. The permanent loss of viscosity during running of the engine on a lead-free fuel was very similar to that obtained when the engine had been driven by an electric motor (Fig. 1). The fuel dilution was less than half per cent. With 'leaded fuel', however, the permanent loss of viscosity was appreciably larger and increased with the lead content of the fuel. Yet, the increase in the temperature coefficient of the viscosity of the oil did not exceed in these cases the increase obtained when the engine had been driven by electric motor (Fig. 2). The temperature coefficient of the viscosity is here:

$$\alpha = \frac{d\ (\log\ \log\ (\nu + 0\cdot6))}{d\ (\log\ T)}$$

where ν is the kinematic viscosity in cS. and T the absolute temperature. This could indicate that a greater number of large molecules was broken down in the presence of lead and that also the reactions

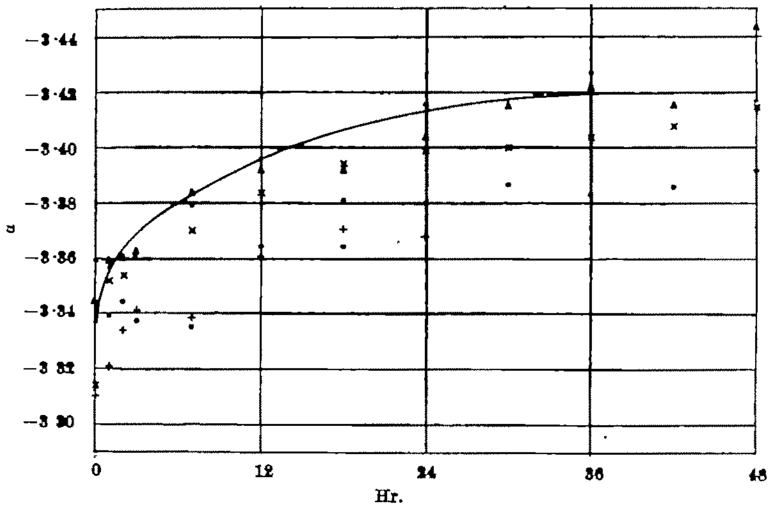

Fig. 2. Viscosity–temperature coefficient of used oil. ●, Engine 'motored'; ○, lead-free fuel; +, fuel containing 0·21 ml. tetraethyl lead/Imp. gallon; ×, fuel containing 1·85 ml. tetraethyl lead/Imp. gallon; Δ, fuel containing 3·57 ml. tetraethyl lead/Imp. gallon

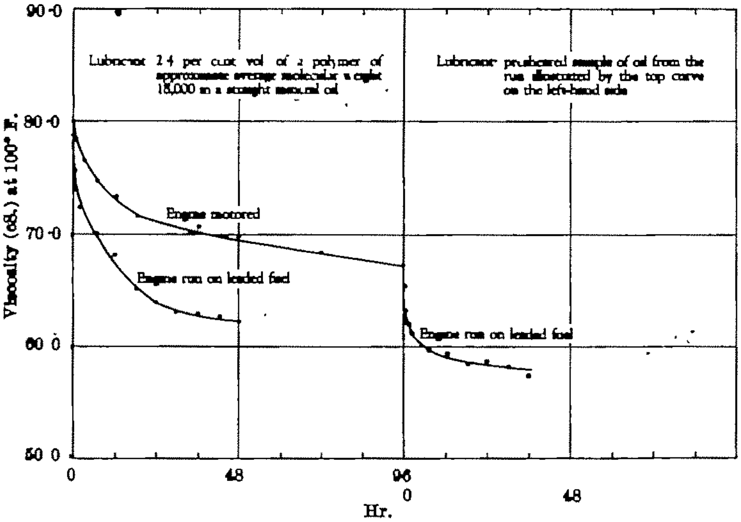

Fig. 3. Permanent loss of viscosity of lubricants

of the free radicals with oxygen molecules were promoted by the presence of lead. In fact, the sludge and acidity of the used oil showed a noticeable increase with the lead content of the fuel on which the engine had been run (Table 1).

Table 1

Sludge and acidity of used oil containing 1·2 per cent volume of a polymer of approximately average molecular weight of 18,000 in a straight mineral oil

Lead content	Duration of run (hr.)	Naphtha insolubles (per cent)	Acidity (mgm. pot. hydrox./gm.)
0	48	0·045	0·05
0·21 ml.*	48	0·18	0·1
1·85 ml.	48	0·16	0·18
3·57 ml.	48	0·19	0·29
Comparison of data from 'motoring' the engine	48	0·06	0·05

* Lead content as ml. tetraethyl lead per Imperial gallon.

Table 2

Permanent loss of viscosity during motoring of an internal combustion engine

Type of polymer	Approximate average molecular weight of polymer	Permanent loss of viscosity (per cent)
Polybutene	900	0
Polyisobutene	18,000	~ 8 (~ 15 on doubling the concentration of the polymer)
Polyisobutene	80,000	~ 43

Table 3

Comparison of the results obtained with an oil containing 2·4 per cent volume of a polymer of approximately average molecular weight 18,000 in a straight mineral oil before and after it had been sheared. In both cases the engine had been run on the same 'leaded fuel'

Lubricant	Initial viscosity (cS.) at: 100° F.	Initial viscosity (cS.) at: 210° F.	Initial viscosity temperature coefficient	Final viscosity (cS.) at: 100° F.	Final viscosity (cS.) at: 210° F.	Final viscosity temperature coefficient
New oil	78·7	11·95	−3·060	62·9	10·02	−3·151
Used oil from 'motoring' the engine for 96 hr.	65·3	9·80	−3·229	57·4	9·12	−3·101

The dependence of the mechanical degradation of the oil for a given shearing stress upon the size and concentration of large molecules was confirmed when the engine was driven by an electric motor (Table 2).

Proof was also obtained that an oil the large molecules of which had previously been degraded by driving the engine for a prolonged period (96 hr.) with an electric motor suffered afterwards very little permanent loss of viscosity while running the engine on a 'leaded fuel' (Fig. 3). Its viscosity-temperature coefficient (Table 3), instead of further increasing, decreased noticeably, while the naphtha insolubles and the acid number increased significantly, from 0·12 to 0·24 per cent and from 0·18 to 0·32 mgm. potassium hydroxide/gm., respectively.

In all these experiments, the engine was run at a speed at which it was estimated that the mean rate of shear in the main bearings was of the order of 10^7 sec.$^{-1}$.

Growth of Sulphide Films on Steel

Sulphur and its compounds are widely used as 'extreme pressure' additives in gear oils. They can prevent scuffing of the gears by the formation of protective sulphide films. The kinetics of the formation of such films at high temperatures is of technological interest, and a study of this problem was made in this Laboratory, using radioactive tracers and electron microscopy.

In order to simulate the brief temperature flashes, which occur when gear teeth mesh, rectangular pulses of electric current were passed through a metal wire, a method of heating previously used in the Thornton Research Centre. The pulses lasted for 4 m.sec. and were followed by periods of 40 m.sec. during which no current was passed. The wire was kept immersed in liquid paraffin, containing sulphur or sulphur compounds, labelled with the isotope sulphur-35. After passing a number of pulses, the radioactivity acquired by the wire was measured. The film thickness was calculated by using a suitable calibration procedure. The wires were 2·5 cm. long and 0·025 cm. diameter and were of mild steel, stainless steel, 'Armco' iron, copper or brass. Pulse temperatures over the range 100–700° C. were used in the experiments. Only the results obtained with mild steel will be discussed here.

It was found that the results followed the generalized parabolic law of film growth[1]:

$$d^2 + k_1 d = k_2 t \qquad (1)$$

where d is the film thickness and t the time of reaction; k_1 and k_2 are constants. For the present experiments it was permissible to substitute N, the number of pulses for t, and the applicability of equation (1) was tested by plotting d versus N/d. Straight lines intersecting the d-axis showed that the law was applicable,

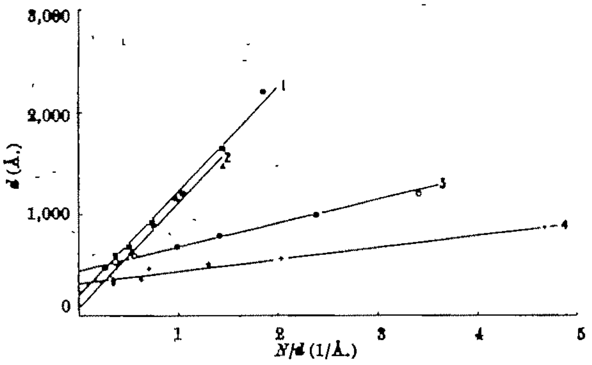

Fig. 1. d, film thickness; N, no. of pulses. Mild steel, pulse temperature, 400° C. 1, 2, dibenzyl sulphide; 3, 4, elemental sulphur

and this is illustrated in Fig. 1. Curves 1 and 2 relate to solutions of dibenzyl disulphide, containing the equivalent of 0·5 and 0·25 per cent by weight of sulphur. Curves 3 and 4 refer to elemental sulphur in similar concentrations. Mild steel wires and pulse temperatures of 400° C. were used in these experiments. The results can be interpreted as follows: during the first few pulses a fast reaction led to the build-up of relatively thick sulphide films (reaction-rate constant k_1). Soon, however, the reaction-rate slowed down and was then governed by a diffusion mechanism, characterized by the constant k_2. The coefficient of diffusion, D, and the energy of activation, ΔE_D, could be calculated from the experimental results. For elemental sulphur solutions and mild steel at 400° C., D was about 5×10^{-12} cm.^{2}/sec. and ΔE_D about 20 kcal./mole.

It seemed important to establish whether, during the initial stages, a uniform film developed over the surface or localized growth occurred. This was investigated using an *E.M.*6 Metropolitan-Vickers electron microscope. Two techniques were employed. Extraction replicas were prepared by evaporating carbon on to the surface of the wire. The film was removed by etching the wire for a short time in 10 per cent nital, then transferring it to distilled water where the film became detached from the wire and was collected in the usual way. Fig. 2a shows a micrograph obtained by this method. Apart from relatively thick regions, a large number of whiskers can be seen. Further information about the structure of the film was obtained by examining sulphided wires directly in the electron microscope. Fig. 2b shows the shadow cast by the edge of a wire. Large-scale growth of sulphide had occurred in a few places (marked *A*). The uppermost surface of these areas of growth shows the roots of the whiskers (marked *B*). The primary film of sulphide formed on the surface is shown not to be uniform and to consist of localized growth terminating in fine whiskers.

METALLURGY

An Iron-Silicon Carbide

Many microconstituents alleged to be iron carbides containing silicon have been reported[1-3]. Marles[4] carried out a systematic microscopic examination of rapidly cooled irons containing up to 7 per cent silicon and 1·7–3·6 per cent carbon. A non-heat-tinting constituent described as a 'silico-carbide' was found associated with cementite. Hurst and Riley[5] found a micro-constituent containing carbon and silicon in rapidly cooled iron–silicon–carbon alloys containing 10–15 per cent silicon. More recently, Owen and Street[6] identified another micro-constituent, believed to be a carbide containing silicon, in slowly cooled high-purity alloys containing 5–8 per cent silicon and small amounts of carbon. This carbide was designated the *X*-constituent.

Previous X-ray work[6] on these carbides failed to detect any similarities in their crystal structure, and the exact structure of each carbide was not ascertained. We have completed a detailed examination of the Marles carbide, the Hurst and Riley carbide and the *X*-constituent in solid and in extracted specimens. Using lithium fluoride monochromated radiation with a Debye–Scherrer technique, we find that all three carbides have the same crystal structure. The unit cell is hexagonal with $a = 11\cdot7$ Å., $c = 10\cdot8$ Å. and $c/a = 0\cdot925$, and no variation of these parameters with composition was detected.

We have attempted to determine the chemical composition of the hexagonal carbide by lineal analysis of selected micro-structures. In addition the carbide has been extracted and chemically analysed by the British Cast Iron Research Association. The general results suggest that the carbide contains approximately 9 per cent silicon and 6·5 per cent carbon, giving a formula for the carbide of $Fe_{10}Si_2C_3$. However, there is considerable scatter in the results, and this formula cannot be taken to be firmly established.

Harry[7] and Leslie *et al.*[8,9] have reported carbides other than cementite in low-carbon silicon steels, containing up to 0·10 per cent carbon and between 3 and 4 per cent silicon. The reported X-ray diffraction and electron diffraction patterns cannot be reconciled with the pattern obtained from the hexagonal carbide reported here.

This work formed part of a larger research which will be described in the *Journal of the Iron and Steel Institute*. The work was supported by the Andrew Carnegie Research Fund.

CHEMISTRY

Ionic-Covalent Bonding in Crystals

IN discussions in the literature regarding bonding in inorganic semiconducting (or insulating) crystals there seems to be some confusion between bond ionicity on one hand and charge separation effects due to electronegativity differences on the other. This appears to have arisen from the common assumption that the ionic component of bonding in solids is determined solely by the electronegativity difference (Δx) between the constituent atoms (that is, that a compound with, say, $\Delta x = 1 \cdot 0$ must be more ionic than one with $\Delta x = 0 \cdot 5$). Without some qualification, this assumption can be very misleading.

Some elementary arguments regarding electronegativity will serve as a useful introduction. This parameter, defined following Mulliken as the mean of the first ionization constant and the electron affinity of an isolated atom, can be considered a measure of relative electron attracting power. It is not, however, a constant since it depends on the orbital employed (for $s - p$ hybrids it has been shown to decrease as the orbital becomes more strongly directed[1]), on the degree of hybridization, and also on the effective ionic charge (increasing with positive charge, decreasing with negative[2]). Most existing scales of electronegativity, incidentally, take little account of these effects.

When atoms with different electronegativities combine, the more electronegative element tends to become negatively charged, which lowers its electronegativity, while the opposite is true of the less-electronegative element; at equilibrium both atoms have the same effective electronegativity[3]. Conversely, if before combination there is no electronegativity difference, no charge transfer will occur. These arguments apply equally to diatomic molecules and to the quasi-infinite molecules in ionic-covalent crystals.

It will be assumed in the following discussion, as a matter of definition, that by a covalent bond is understood one in which the bonding electrons are equally shared between the bonded atoms, and by an ionic bond one in which they are associated solely with the electronegative constituent[1,4]. It will also be assumed that continuous linear variation in bonding electron distribution is possible between the two extreme forms, and that effects associated with overlap can be neglected.

Applying the previous arguments to a typical ionic-covalent crystal, zinc sulphide, it follows that no charge separation would take place if zinc and sulphur, as free atoms, had the same electronegativities. In this case each atom in the lattice would have its normal complement of valence electrons associated with it (zinc two, sulphur six).

Such an electron distribution gives the 'neutral' formulation $Zn^{0}S^{0}$, which is to be compared with the extreme covalent formulation Zn^{2-}–S^{2+} (equal sharing of the electrons, see, for example, Pauling[4]), and ionic formulation $Zn^{2+}S^{2-}$ (electrons associated solely with the electronegative constituent).

It will be noted that, lying exactly midway between these extremes, the 'neutral' bonds of $Zn^{0}S^{0}$ would be formally 50 per cent ionic (or 50 per cent covalent), that is, with equal contributions from covalent and ionic forms.

Neutral bonds of this type, however, would only be formed in the absence of any difference in electronegativities. Sulphur has in fact a considerably higher electronegativity than zinc, so that in crystalline zinc sulphide charge separation will take place with respect to the neutral bond state, the sulphur atoms becoming negatively charged and the bonds becoming more than 50 per cent ionic.

This simple approach (which appears first to have been pointed out some years ago[5]) is capable of general application to ionic-covalent solids (and also to dative bonds in simpler molecules), since in all cases the neutral bond state is the natural zero point for charge separation arising from electronegativity differences. If only one type of bond is present in the lattice the neutral bond state can be deduced by inspection. Thus for all $A^{II}X^{VI}$ compounds (of which zinc sulphate is an example) it occurs at 50 per cent ionic bonding, for $A^{I}X^{VII}$ compounds such as sodium chloride (covalent form A^{I3-}–X^{VII3+}, ionic form $A^{I1+}X^{VII1-}$) at 75 per cent, and for $A^{III}X^{V}$ compounds such as aluminium nitride (covalent form A^{III1-}–X^{V1+}, ionic form $A^{III3+}X^{V3-}$) at 25 per cent. For more complex compounds in which more than one type of bond is present each type can be assigned its specific neutral-bond ionicity independently. The actual bonds in compounds will of course depart from the neutral form(s) to an extent dependent on the appropriate electronegativity difference(s).

This raises the problem of what scale of electronegativity is applicable to solids. It is not proposed to discuss this matter in any detail, but the following observations appear pertinent.

In principle there is a separate electronegativity scale for every type of bonding orbital, equally applicable to atoms in solids or in simpler molecules. The relative order of the elements should show little variation from scale to scale, but, as mentioned above, absolute electronegativity values can change with directivity or hybridization of bonding orbital. It would seem, however, that even between extreme cases this change is unlikely to exceed 0·5 unit, so that Pauling-type scales are probably not grossly misleading (particularly for large electronegativity differences) if one wishes to obtain some idea of the sign and relative extent of charge separation. (It should be noted, however, that there are in any event errors arising in determining Pauling type electronegativities which are probably of the order of ± 0·1 unit or more.) The Sanderson scale[6,7], for tetrahedral co-ordination, also appears of interest since it is apparently derived for the case of a single bonding orbital.

Finally, even for simple molecules there appears to be no reliable relationship between charge separation and electronegativity difference, and little attempt has been made to establish one for solids. In this connexion the alkali halides, with an electronegativity difference of ~ 2 units, must presumably show separation of, effectively, a whole electronic charge. Perhaps values for smaller electronegativity differences may eventually be deduced from reststrahlen frequency measurements, but, as pointed out by Matossi[8] and others, this approach is not promising. For the present one can only assume a monotonic increase of charge separation with electronegativity difference.

Some examples to illustrate these points follow:

Consider the isoelectronic pair sodium fluoride ($A^{\mathrm{I}}X^{\mathrm{VII}}$ group) and magnesium oxide ($A^{\mathrm{II}}X^{\mathrm{VI}}$ group). Neutral-bonded sodium fluoride would be 75 per cent ionic (see above); the large difference in the electronegativities of sodium and fluorine brings about the transfer of presumably about a whole unit of charge to make the real sodium chloride lattice almost 100 per cent ionic. In contrast neutral-bonded magnesium oxide is 50 per cent ionic, and, with a much smaller electronegativity difference than for Na—F, the real magnesium oxide lattice is unlikely to be even 75 per cent ionic (the appreciable covalency of its bonds gives magnesium oxide very different properties from sodium fluoride, for example hardness).

With regard to semiconducting compounds the present approach indicates that III–V zinc blende compounds are all more than 25 per cent ionic while the related II–VI compounds (like zinc sulphide) must be more than 50 per cent ionic. This is in agreement with microcleavage data[9] and, for the case of gallium arsenide, with estimates based on an analysis of spin-orbit splitting in infra-red transmission spectra[10].

Pyrites (FeS_2) is a simple example of more complex compounds in which more than one kind of bond may be present. The S—S bonds in pyrites can be assumed covalent, leaving 12 electrons for 6 Fe—S bonds[11]. Only two of these 'belong' to Fe, so that the neutral form of the Fe—S bond is 2/6 (that is, 33·3 per cent) covalent. The actual difference in the electronegativities of Fe and S will further reduce this covalent contribution in the real lattice, but will have no comparable effect on the S—S bonds.

Generally compounds tend to be more ionic than the neutral-bonded form since, as would be expected, 'anionic' elements usually have higher electronegativities than 'cationic' elements. (It should be noted that HgTe may be an exception since the appropriate electronegativity difference is only 0·2 unit, which is within the limit of accuracy of available electronegativity scales. Similar arguments may also apply to As_2Te_3. Electronegativity values are taken from Haissinsky[12].)

From many points of view it would appear useful to differentiate two ionic components of bonding in solids: structural ionicity associated with a neutral-bond structure, and charge separation ionicity arising from electronegativity differences. It is the second of these which is responsible for optical scattering of charge carriers in semiconductors, and, to some extent at least, for the difference between high- and low-frequency dielectric constants in 'ionic' crystals (in connexion with the latter effect, the simple approach here outlined should enable the sign of the charge separation to be deduced, a matter of argument in the past). Both components must be taken into account when considering bond-strength and related properties.

Optically Active Forms of a Derivative of Tetra-substituted Sulphur

THE concept of the configuration of unevenly tri-substituted sulphur derivatives as an incipient tetrahedron is borne out by both physical studies and resolutions; but the evidence for the tetrahedral structure of tetra-substituted sulphur rests solely on physical investigations.

The simplest member of a new class of sulphur compound, dimethyl sulphoximine, was first prepared by permanganate oxidation of *SS*-dimethyl-*N*-toluene-*p*-sulphonylsulphidimine to *SS*-dimethyl-*N*-toluene-*p*-sulphonylsulphoximine, followed by acid hydrolysis[1]. As part of a study of an optically active chloramine-*T*, one stereoisomer of sodium-4-(3-menthyl)-benzenesulphonchloramide, it seemed of interest to attempt its conversion to the sulphoximide of a mixed sulphide in order to investigate possible isomerism of the *dC.dS*. and *dC.lS*. type, suggested by the following facts. The sulphur–nitrogen linkage, in the sulphidimine, and the sulphoxide bond are stereochemically analogous[2,3], and oxidation of the latter gives sulphones which are known to have an approximately tetrahedral structure[4].

Model experiments confirmed the previous observations of the instability of sulphidimines of mixed sulphides, bearing more complex substituents than dimethyl, under oxidizing conditions[2,5]. Chloramine-*T* and *p*-nitrophenylmethylsulphide gave the normal sulphidimine, m.p. 161°; identical material resulting from the condensation of *p*-toluenesulphonamide with *p*-nitrophenylmethyl sulphoxide, in presence of phosphorus pentoxide[6]. Treatment of this sulphidimine with permanganate under various conditions only gave starting material or *p*-toluenesulphonamide.

The oxidation product was eventually obtained by condensing, in dry pyridine, toluene-*p*-sulphonylchloride with the basic *p*-nitrophenylmethylsulphoximine[7] (prepared by the more general route of treating the sulphoxide with hydrazoic acid), giving the required sulphoximide as a neutral stable compound, m.p. 203–204°. The infra-red spectra showed nitro-adsorption at 6·6 and 7·4μ and strong bands at 7·7, 8·1, 8·7 and 9·2μ, which are also the principal bands in the spectra of the *SS*-dimethyl-*N*-toluene-*p*-sulphonylsulphoximine, and compared with the spectra of the *p*-nitrophenylmethylsulphidimine showed shifts in the position of the major bands identical to those observed between the spectra of the dimethyl analogues.

Condensation of the optically active 4-(3-menthyl)-benzenesulphonylchloride, m.p. 13°, $[\alpha]_{5461}^{24} + 64\cdot6°$, obtained by suitable treatment of an optically pure strychnine 4-(3′-menthyl)-benzenesulphonate with *p*-nitrophenylmethylsulphoximine gave *S*-*p*-nitrophenyl-*S*-methyl-*N*-[4-(3-menthyl)-benzenesulphonyl]-sulphoximine as a mixture of diastereoisomerides, m.p. 133–136°, $[\alpha]_{5461}^{24} + 34\cdot0°$, which showed large changes of rotatory power on recrystallization. The less-soluble form, thick hexagonal plates from methanol–chloroform, had m.p. 150°, $[\alpha]_{5461}^{21} - 155°$, $[\alpha]_{D}^{21} - 124°$. (Found: C, 57·7; H, 6·2; N, 6·0; S, 13·5. $C_{23}H_{30}O_5N_2S_2$ requires C, 57·7; H, 6·3; N, 5·9; S, 13·4 per cent). Systematic fractionation of the mother-liquor has given an extreme crop, m.p. 138–140°, $[\alpha]_{5461}^{19} + 171\cdot9°$, $[\alpha]_{D}^{19} + 138°$. (Found: C, 57·6; H, 6·3; N, 6·1; S, 13·1 per cent.) The infra-red spectra of the diastereoisomers were almost identical and showed the characteristic sulphoximide adsorption.

These results give an indication of asymmetry at the tetrasubstituted sulphur atom and therefore it seems that, like the sulphones and sulphuryl halides[4], this class of sulphur compound has a tetrahedral structure.

I thank the Council of Bedford College for a post-graduate studentship, Dr. D. G. H. Daniels, and the Research Director of the Research Association of the British Flour-Millers for specimens of the dimethyl sulphidimine and sulphoximide for infra-red comparison, and Mr. J. F. Robinson for technical assistance.

A New Method for the Synthesis of Cyclic Ethers

HETEROCYCLIC compounds having four members in the ring are difficult to prepare, and are generally less well known than the 3-, 5- and 6-membered rings of the same type. In the cyclic ethers, for example, oxetanes have been studied relatively little compared to oxiranes and tetrahydrofurans.

The oxetanes have considerable potential as chemical intermediates and solvents provided that they could be made economically. For example, oxetane polymers, particularly from 2,2-disubstituted oxetanes, have interesting properties. However, most of the known syntheses of oxetanes are tedious, expensive and give moderate yields, at best[1]. The only exceptions are the ring closures involving the trihalo derivatives of pentaerythritol[2] and the pyrolysis of hydroxy-cyclic carbonates[3].

Recently[4], a new, general synthesis of oxetanes has been reported. This synthesis is a direct, cheap process giving fair yields, and it has been further investigated to determine its scope and limitations.

The synthetic procedure is simple. A diol with the hydroxy groups separated by 3 carbons is dissolved in concentrated sulphuric acid. The mixture is dropped into a boiling solution of aqueous caustic. The product oxetane distils over as it is formed. The distillate separates into two layers, as a general rule. The ether is salted out of the aqueous phase, dried over calcium hydride, and distilled. The procedure is also useful for the preparation of other cyclic ethers, such as tetrahydrofurans and tetrahydropyrans.

The various oxetanes which have been made by this procedure are listed in Table 1. In all runs, 55·5 ml. of 98 per cent sulphuric acid was used to dissolve the diol.

Table 1. CYCLIC ETHERS

Diol (gm.)	Caustic (gm. and per cent)	Product (gm.)	Boiling point (° C.)
Neopentyl glycol (104)	240 (55)	2,2-dimethyl oxetane (24·5)	79·2–80·3
2-Butyl, 2-ethyl 1,3-propanediol (142)	240 (55)	2-butyl, 2-ethyl oxetane (44·4)	181·2–183·9
1,3-Butanediol (90)	240 (64)	1-methyl oxetane (about 15)	58–61
2 Ethyl-1,3 hexanediol (146)	240 (55)	1-*n*-propyl, 2-ethyl oxetane (24·3)	152·5–155·5
2,2-Diethyl 1,3-propanediol (132)	240 (55)	2,2-diethyl oxetane (38·3)	139–141
1,4 Butanediol (90)	240 (55)	tetrahydrofuran (47·1)	
1,5 Pentanediol (104)	240 (55)	tetrahydropyran (85·4)	
2,5-Dimethyl, 2,5-hexanediol (146)	240 (55)	2,2,5,5-tetramethyl tetrahydrofuran (87·3)	110–112

In an attempt to obtain an optimum yield of 2,2-dimethyl oxetane from this synthesis, a factorial experiment was run, in which the factors were the following:

Acid, strength: 98 per cent, oleum.
Acid, quantity: equimolar, 50 per cent excess with respect to glycol.
Base, strength: 40 per cent, 70 per cent.
Base, quantity: stoichiometric, 50 per cent excess with respect to acid.

The results of the experiment, together with replications, are given in Table 2. The values are grams of product obtained from 208 gm. neopentyl glycol as starting material.

Table 2. FACTORIAL DESIGN USED TO DETERMINE SIGNIFICANCE OF VARIABLES

Sodium hydroxide		Sulphuric acid H_2SO_4 Stoichiometric	Sulphuric acid H_2SO_4 50 per cent excess acid	H_2SO_4-Oleum Stoichiometric	H_2SO_4-Oleum 50 per cent excess acid
Initial 70 wt. per cent conc.	50 per cent excess caustic	49·2 46·0	37·1 31·3	48·1	36·4
	Stoichiometric	16·2	19·9	13·1	14·6
Initial 40 wt. per cent conc.	50 per cent excess caustic	7·8	11·5	5·6	13·7 21·5
	Stoichiometric	7·0	2·0 2·3	2·0	3·9

An analysis of variance of the factorial experiment shows that only the amount of caustic, the concentration of caustic, and their interaction have significant effects on the yield of oxetane.

Because of the nature of the process, it is felt that the instantaneous concentration of caustic is the variable actually affecting the yield of oxetane. The amount of excess base only affects the range of concentrations during a run. In another experiment, a number of runs were made at varying concentra-

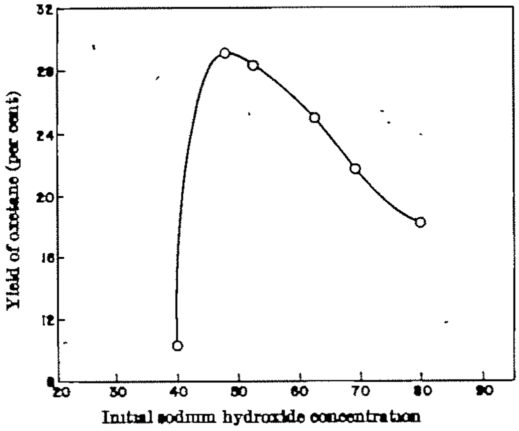

Fig. 1. Effect of sodium hydroxide concentration upon the yield of 3,3-dimethyloxetane

tions of caustic. In each case, 200 per cent excess caustic was used so that the concentration of base remained fairly constant during the run. The results are given in Fig. 1. It is seen that the maximum yield of oxetane occurs at an initial concentration of base of about 50 per cent.

Since the yield of oxetane is relatively low, and since only small amounts of non-condensable by-products were noted, the composition of the residual solution was briefly investigated. In one experiment, using 104 gm. neopentyl glycol, 55·5 ml. sulphuric acid, and 480 gm. of 50 per cent sodium hydroxide, 21·2 gm. of dimethyl oxetane was produced. The residual solution was neutralized with sulphuric acid and extracted with ether. A total of 38 gm. of material was recovered from the extracts. This material appeared to be substantially unchanged neopentyl glycol.

In another experiment, using 208 gm. neopentyl glycol, 111 ml. sulphuric acid and 440 gm. of 54·5 per cent caustic, 53 gm. of dimethyl oxetane was produced, and 73 gm. of crude glycol was recovered by a chloroform extraction of the diluted and filtered residue. The recovered glycol was distilled, and 50 gm. of the material came over between 200° and 207° C. A few grams of residue remained when decomposition began. The results of the two experiments are seen to be quite similar. In the latter experiment, 135 gm. of glycol was consumed, a conversion of 65 per cent; the yield of product is 53 gm., or 47 per cent, based on the amount of glycol actually used up.

It was noted that additional material could be recovered by a chloroform extraction of the residual solution, after the solution had been neutralized with sulphuric acid. This material was recovered as a viscous liquid, which slowly crystallized, and was clearly not neopentyl glycol. Because of the limited solubility of this material in chloroform, it was not quantitatively recovered.

About 30 gm. of crystalline material, of moderate solubility in water, insoluble in chloroform and acetone, and having an infra-red spectrum consistent with an ionic sulphonate, was isolated from the run in the factorial experiment made with 50 per cent excess oleum, and 50 per cent excess of 70 per cent caustic. This material was not further identified. Presumably, the formation of this, and similar materials, accounts for the greater part of converted glycol not appearing as oxetane. As already noted, very little volatile by-product is formed. Further work is in progress to identify these side-products and to obtain a complete material balance, as well as to improve the yields of cyclic ethers.

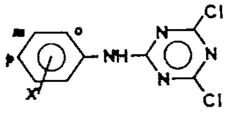
An *Ortho* Effect influencing Fungitoxicity, Electronic Absorption Spectra, and Chemical Reactivity with Mercaptalbumin

The derivative of 2,4-dichloro-6-anilino-*s*-triazine containing a chlorine atom in the benzene ring *ortho* to the imino group is less toxic to conidia of *Neurospora sitophila* (Mont.) Shear and Dodge than the corresponding *meta* or *para* isomer[1].



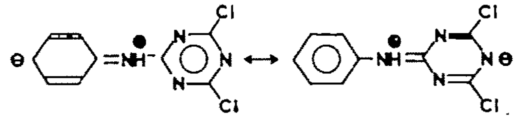
The principal effect of *ortho* substitution is to reduce the amount of toxicant taken up by the fungus spores from the ambient solution, the *ED*50 values of the three compounds being approximately the same on a spore-weight basis. More recent results obtained on conidia of *N. sitophila* reveal that the same order of uptake is followed when the substituent group is methyl or ethoxy (Table 1), and that substitution of the imino hydrogen on the bridge connecting the aromatic and heterocyclic rings with a methyl group also reduces accumulation of the chemical by the spores. The effect is greatest when both an *ortho* hydrogen and the imino hydrogen are replaced by methyl groups. In this case only 15 per cent of the applied dose is taken up compared to 77 per cent for the *p*-methyl derivative. The same pattern is also found for the uptake of these compounds by conidia of *Myrothecium verrucaria* (Alb. and Schw.) Ditm. ex Fr., *Glomerella cingulata* (St.) Sp. and von S., and *Aspergillus niger* van Tiegh.

These observations suggest that maximum uptake of the triazine is obtained when the aromatic and heterocyclic rings can assume a coplanar configuration, since bulky groups in an *ortho* position of the benzene ring or on the bridge nitrogen would interfere with free rotation through van der Waals repulsion

Table 1. Influence of Isomerism on the Uptake of *s*-Triazine Derivatives by Conidia of *N. sitophila* at Applied Doses of 6 Micromols per Gram of Spores

Substituent(s)	Percentage of isomer taken up: *Ortho*	*Meta*	*Para*
Cl	81	86	87
C_2H_5O	55	78	74
CH_3	53	75	77
N—CH_3, CH_3	15	40	48

forces and steric hindrance. An alternative hypothesis is that *ortho* substituents might decrease binding to metabolic substrates by interfering with the formation of hydrogen bonds between the imino group and electron- or proton-donating groups at receptor sites within the spores. In either case it should be possible to demonstrate crowding at the imino bridge through changes in electronic absorption spectra, since substituents that reduce degree of coplanarity would concomitantly reduce interannular resonance. This would result in a shift of absorption maxima to shorter wave-lengths and lower molar extinction coefficients, since absorption of radiation by these compounds arises predominantly from $\pi - \pi^*$ transitions. In particular, the weights of ionic valence-bond structures of the following type in predicting electron density distribution in the resonance hybrid would be reduced:



On comparing the electronic spectra of *s*-triazines substituted in various positions with methyl groups, it can be seen that *ortho* substitution produces a hypsochromic shift of 32 mμ coupled with lowering of intensity when the solvent is acetonitrile (Table 2). Substitution on the imino group causes a blue shift of 25 mμ, but the molar extinction is not changed appreciably. In *cyclo*hexane solution, the blue shift arising from *ortho* substitution is only 3 mμ, but the molar extinction coefficient is reduced by 20 per cent. The *N*-substituted isomer exhibits a pronounced blue shift in both solvents. By contrast, small red shifts occur in both the polar and non-polar solvents when methyl groups are substituted for hydrogen in the *meta* or *para* positions. Similar results are obtained when chlorine atoms and ethoxy groups are substituted in the aromatic ring, indicating that bulky *ortho* substituents reduce conjugation. This is highly correlated with the amounts of these compounds that are taken up by fungus spores.

Table 2. ELECTRONIC ABSORPTION DATA ON *s*-TRIAZINE DERIVATIVES IN *cyclo*HEXANE AND ACETONITRILE

Substituent	Acetonitrile λ_{max}	Acetonitrile ε	*Cyclo*hexane $\lambda_{max.}$	*Cyclo*hexane ε
None	269	17,700	271	18,900
o-Methyl	237	14,200	268	13,300
m-Methyl	271	16,900	275	19,300
p-Methyl	273	17,500	276	19,900
N-Methyl	244	17,300	245	16,100

Concurrent studies on the kinetics of the nucleophilic substitution reactions that take place between the *s*-triazines and bovine mercaptalbumin[2] indicate that an *ortho* effect occurs here as well, the *o*-methyl isomer being only about 10 per cent as reactive with the protein as the *meta* and *para* isomers. It is unlikely that this results from a higher energy of activation in the reaction of the *ortho* isomer with mercaptalbumin, since the second-order velocity coefficients for the reactions of the three isomers with glycine are about the same. Steric effects are unlikely to be involved to a major extent in this latter case, because of the small size of the glycine molecule. Therefore the net electron-releasing power of the methyl group, arising from induction and hyperconjugation, has the same order of magnitude at all three positions in the aromatic ring, leaving steric hindrance as the only way to account for the low reactivity of the *ortho* isomer with the protein.

At present it is not clear whether the *ortho* effects demonstrated in the interactions of the *s*-triazines with fungus spores and the animal protein arise from a reduction in degree of coplanarity of the rings, or steric hindrance of hydrogen bonding at the imino group, or both. However, the possibility that *s*-triazines of this type can form hydrogen bonds with metabolic substrates is supported by the finding that the *o*-methyl isomer is significantly less reactive with tyrosine than the *meta* and *para* compounds, perhaps because hydrogen bonding of the imino groups of the latter molecules with the phenolic hydroxyl group of the tyrosine speeds up the reactions by a Michaelis–Menton type mechanism.

RADIOCHEMISTRY

Non-destructive Analysis of Selenium by Neutron Activation followed by Gamma-Ray Spectrometry

DETECTION of selenium by neutron irradiation and gamma scintillation spectrometry has been attempted. It is known that, when natural selenium is irradiated with neutrons, selenium-75 (121 days), selenium-77 *m* (17·5 sec.) and selenium-81 (18·2 min.) are formed with comparatively large cross-sections. When any one of them is used to detect selenium, irradiation must be continued for a period comparable to the half-life. Therefore, it was thought that the use of selenium-77 *m* offered a method for the rapid detection of selenium; this method has not been described in the literature examined.

In the present work, the sample (0·1–0·5 gm.) was irradiated at a neutron flux of 3×10^{11} neutrons per sq. cm. per sec. for 20 sec., cooled for 15 sec., counted for 20 sec., again cooled for 20 sec. and counted for 20 sec. The counting apparatus used was a 256-channel pulse-height analyser with a 2-in. thick, well-type sodium iodide crystal. A typical spectrogram thus obtained is shown in Fig. 1, from which it is seen that: (1) there is only one photopeak;

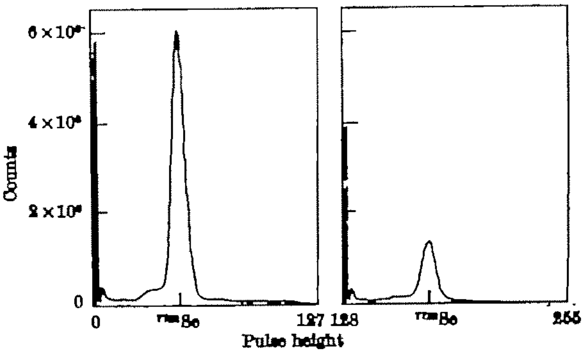

Fig. 1. Typical spectrogram. Sample, 0·109 gm. of sulphur powder. Energy scale ≃ 3·3 keV./pulse-height unit

Table 1. RADIONUCLIDES FORMED, THE GAMMA-RAY ENERGY OF WHICH IS ABOUT 0·16 MEV. (ARRANGED BY INCREASING HALF-LIFE)

Nuclide formed	Half-life	Nuclide formed	Half-life
^{183m}W	5·5 sec.	^{233}Th	22 min.
^{77m}Se	17·5 sec.	^{131}Te	25 min.
^{179m}Hf	19 sec.	^{123}Sn	40 min.
^{77m}Ge	54 sec.	^{111m}Cd	49 min.
^{165m}Dy	1·25 min.	^{139}Ba	84 min.
^{185m}W	1·62 min.	^{177}Yb	1·9 hr.
^{161}Gd	3·6 min.	^{85m}Kr	4·4 hr.
^{182m}Ta	16·5 min.	^{188}Re	17 hr.
^{70}Ga	21 min.		

(2) the corresponding gamma-ray energy is in the range 0·15$_5$–0·17 MeV.; (3) the half-life of the photopeak is about 17·5 sec.

Radionuclides formed by neutron irradiation from naturally occurring nuclides, and with gamma-ray energy of about 0·16 MeV., are shown in Table 1.

Of these radionuclides, those which show similar shapes of the gamma-spectra of Fig. 1 are selenium-77 *m*, tantalum-182 *m*, tin-123 and barium-139. Their half-lives are 17·5 sec., 16·5 min., 39·5 min. and 84 min., respectively.

By the comparison of observed half-life with the values given above, selenium can be identified, and it is confirmed that the observed photopeak is due to selenium.

Table 2. RESULTS OF ANALYSES

Sample	Selenium found (p.p.m.)
A (Sulphur)	68
B (Sulphur ore)	6·8
C (Ammonium thiocyanate)	< 0·02
D (Ammonium sulphate)	< 0·05

For the purpose of quantitative determination, the relation between photopeak height and the amount of selenium can be obtained by use of standards containing selenium in various amounts ranging from 0·1 to 100 μgm. (see Table 2).

I am indebted to Prof. Shozi Makishima for helpful suggestions, to Dr. Toshio Nakai for permission to use laboratory facilities, and to Dr. Seishi Yajima for help with the gamma-spectra.

BIOCHEMISTRY

Reactivity of the Disulphide Bond in Wool

THE permanent set which strained wool fibres acquire in steam or boiling water is due to breakdown of disulphide bonds; this promotes dissipation of stress, followed by linkage rebuilding, which fixes the relaxed structure in its deformed state. In such conditions oxidized fibres are more difficult to set than untreated, and it has been suggested that the formation of intermediate oxidation products, such as the sulphone, is sufficient to impair setting power[1]. This view has now been confirmed by taking advantage of the observation that sulphur dioxide can be reduced to sulphur by hypophosphorous acid[2].

Lincoln wool fibres were treated with a large excess of 2-vol. hydrogen peroxide for 3 hr. at *p*H 9·4 (borate buffer) and 50° C. After overnight washing in running water, the fibres were rinsed in several changes of distilled water, immersed in 0·05 *M* hypophosphorous acid at 50° C. for various times, and again washed to remove the acid. Fibres from each lot of wool were then stretched 40 per cent in cold distilled water, immersed in boiling distilled water for 1 hr., and finally released in boiling distilled water for 1 hr. Values for the set retained by the fibres are given in Table 1; corresponding values for unoxidised fibres, which had been treated with hypophosphorous acid under similar conditions, are also included. Each result is the average of the values obtained with at least three fibres.

Table 1

Time of treatment with hypophosphorous acid (min.)	Percentage set of.	
	Untreated fibres	Oxidized fibres
0	9·7	−6·2
75	—	3·4
150	—	6·2
180	17·0	—
270	—	7·2
400	—	9·4
660	17·8	12·9
960	19·4	16·8

It seems clear that the ability of hypophosphorous acid to restore setting power to oxidized fibres is due to the reduction of intermediate oxidation products to disulphide cross-linkages, because, whereas the oxidized wool failed to blacken during boiling for 40 min. in lead acetate solution at *p*H 4·9 (ref. 3), the same wool, after treatment with hypophosphorous acid for 16 hr., blackened rather more than untreated wool. This result cannot be due to the reduction of cystine cross-linkages to cysteine side-chains, because wool fibres do not supercontract, and strained fibres fail to acquire a set, on being boiled for 30 min. in 0·05 *M* hypophosphorous acid.

The effect of hypophosphorous acid in increasing the setting power of untreated fibres must likewise be due to the reduction of the intermediate oxidation products formed by the action of light and air on the cystine linkages during the growth of the fibres. The presence of such oxidation products to variable degrees in normal fibres, and to different extents in different wools, depending on the conditions to which they were exposed during growth, is one cause of the erratic results obtained in setting fibres under conditions (steam or boiling water) which are far removed from the optimum. Their presence may provide a reason, also, for the failure to account for the whole of the sulphur in keratin in terms of cystine, cysteine, lanthionine and methionine.

As regards the chemical mechanism of setting, the differences of behaviour between untreated and oxidized fibres provide a striking proof that the

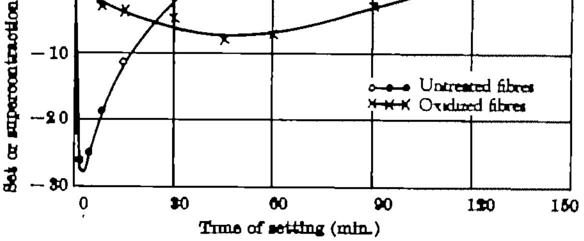

Fig. 1

breakdown of disulphide bonds is an essential first step. As before, the fibres were stretched 40 per cent, and after being immersed in boiling water for various times were released in boiling water for 1 hr. The amounts of set retained by untreated and oxidized fibres are shown in Fig. 1. As would be expected, in view of the greater stability of the intermediate oxidation products of cystine in boiling water[4], the oxidized fibres supercontract to a much smaller extent and are set much more slowly than the untreated fibres, which contain a high proportion of the more vulnerable cystine cross-linkages. In the light of these results, there can be little doubt that the failure of fibres treated with nitric acid to supercontract and set in boiling water[5] is due mainly to the oxidation of the cystine cross-linkages to more stable sulphones.

Finally, it should be mentioned that oxidized fibres can be set readily in boiling dilute solutions of sodium bisulphite, borax and sodium hypophosphite, in accordance with the fact that the intermediate oxidation products of cystine undergo fission readily in bisulphite and alkalis.

Structures of Some Acetyl-serine Peptides from Acetyl-chymotrypsin

IN 1958, two of us[1] obtained, by enzymic degradation of acetyl-chymotrypsin labelled with carbon-14[2], five peptides containing labelled acetyl-groups. Subsequent sequence studies[3] have shown that the largest of these peptides has the amino-acid sequence, Gly·Asp·Ser·Gly·Gly·Pro·Leu, identical with that already found[4], by degradation of the di-*iso*propylphosphoryl-enzyme, to surround the reactive serine; it may reasonably be concluded that the other four peptides contain the sequences Ser·Gly·Gly·Pro·Leu, Asp·Ser·Gly·Gly, Gly·Asp·Ser·Gly and Ser·Gly·Gly, respectively.

Since such studies cannot, on their own, show whether the acetyl-group is attached to an amino- or a hydroxyl-group in the serine residue, two others of us[5] synthesized the four peptides, (I)–(IV): (I) Ac·Ser(OH)·Gly·Gly·OH, (II) H·Ser(OAc)·Gly·Gly·OH, (III) Ac·Ser(O·Asp·H)·Gly·Gly·OH, (IV) H·Asp·Ser(OAc)·Gly·Gly·OH, with the object of comparing them with two of the smaller peptides obtained from acetyl-chymotrypsin. We now report the results of our joint work; the details of the synthetic work and of the sequence studies will be published elsewhere[3,5].

Owing to the low yields in which the smaller peptides are obtained by degradation of acetyl-chymotrypsin, direct comparison with the synthetic products was not possible. However, the behaviour of the two synthetic acetyl-tripeptides on electrophoresis (Table 1) clearly shows that, as is to be expected, only the N-acetyl-tripeptide (I) resembles the acetyl-tripeptide from acetyl-chymotrypsin in being negatively charged at *p*H 3·6 as well as at *p*H 6·5. Clearly the acetyl-tripeptide from acetyl-chymotrypsin is N-acetyl-seryl-glycyl-glycine (I), and not the O-acetyl-compound (II).

Table 1. ELECTROPHORESIS OF SOME ACETYL-SERINE PEPTIDES

(IV)	+2·4	+15·2
Glucose control	0·0	+3·5

Paper electrophoresis, in pyridine–acetate buffer, for 1 hr. at 2,000 V./40 cm. The figures are distances migrated, in mm., towards the anode (+) or cathode (−).

It will be seen, from Table 1, that the two acetyl-tetrapeptides (III) and (IV) are electrophoretically indistinguishable. They were equally indistinguishable by paper chromatography in a number of solvent systems, and recourse had, therefore, to be made to reaction with hydroxylamine as a method for distinguishing such isomeric pairs of acetyl-peptides; this reagent splits the O-acyl linkage, only O-acetyl peptides giving the readily detected acetohydroxamic acid.

The experimental procedure was as follows. A solution of hydroxylamine was prepared by mixing solutions of potassium hydroxide (560 mgm.) in methanol (5 ml.) and of hydroxylamine hydrochloride (347 mgm.) in methanol (5 ml.) and removing the precipitated potassium chloride by centrifugation. This reagent (10 µl.) was heated for 1 min. at 100° with 50 µl. of an aqueous solution containing the acetyl-peptide (0·1 µmole); after cooling, a few drops of methanol were added and the resulting solution acidified (*p*H 6). After paper chromatography, acetohydroxamic acid was detected by spraying with an alcoholic solution of ferric chloride (1 per cent) and hydrochloric acid (1 per cent), appearing as a red spot, $R_F = 0{\cdot}89$ (in t-BuOH : HCO_2H : H_2O; 70 : 15 : 15), 0·45 (in *n*-butanol saturated with water); in the case of acetyl-peptides labelled with carbon-14, the chromatograms were also kept in contact with Kodak X-ray film, material containing carbon-14 being detected by darkening of the developed film. Appropriate markers were run in all cases.

Under these conditions, the synthetic O-acetyl-peptides, (II) and (IV), gave acetohydroxamic acid; the N-acetyl-tripeptide, (I), gave no hydroxamic acid, while the O-aspartyl-N-acetyl-peptide, (III), gave a hydroxamic acid, $R_F = 0{\cdot}26$ and 0·06 (in the two solvent systems), which was undoubtedly aspartyl-α-hydroxamic acid. Treated in the same way, the acetyl-pentapeptide ($R_F = 0{\cdot}94$ and 0·06) from acetyl-chymotrypsin gave no acetohydroxamic acid, the only radioactive material in the reaction product being the unchanged pentapeptide which is, therefore, an N-acetyl-compound; the acetyl-heptapeptide ($R_F = 0{\cdot}80$ and 0·01), however, gave acetohydroxamic acid as the sole radioactive reaction product; clearly, this peptide is an O-acetyl-compound.

Summarizing our results, it appears that, of the acetyl-serine peptides obtained by degradation of acetyl-chymotrypsin, the two which have N-terminal serine residues are N-acetyl-compounds, whereas those with other N-terminal residues are O-acetyl-compounds.

At the outset of our work it was hoped that it might afford a crucial test of the oxazoline hypothesis concerning the nature of the reactive serine in chymotrypsin and other, similar, esterases[6], since it was thought that it was only by the hydrolysis of an N-acetyl-oxazoline that N-acetyl-serine peptides could arise. However, direct experiment[5] has shown that at pH 7·8 and 37°, conditions obtaining in the second stage of the enzymic degradation of acetyl-chymotrypsin[1], the O-acetyl-tripeptide (II), is converted, within 9 hr., into the N-acetyl-tripeptide (I), and that the N-acetyl-O-peptide (III) is broken down into aspartic acid and the N-acetyl-tripeptide (I). In consequence of these findings, our conclusions concerning the structures of the acetyl-serine peptides obtained from acetyl-chymotrypsin can be explained equally well on the basis of the oxazoline[6] and histidine-activation[7] hypotheses concerning the reactive serine. Thus, on the basis of the oxazoline hypothesis, the tautomeric acetylated oxazoline may be expected to break down, on hydrolysis, to give, initially, both N-acetyl-O-peptides, such as (III), and O-acetyl-N-peptides, such as (IV); the former will, however, under the degradation conditions, break down further to give N-acetyl-peptides containing N-terminal serine residues, which will, in agreement with our results, be the only isolabile N-acetyl-peptides. Likewise, although the histidine-activation hypothesis requires that only O-acetyl-peptides should be formed initially, those containing N-terminal serine will isomerize, under the degradation conditions, to N-acetyl-peptides, again in agreement with our findings. Our results cannot, therefore, be used to discriminate between the two hypotheses; for this purpose, different methods of approach are required, and work of this kind is in progress in both our laboratories.

We thank the University of Exeter for the award of an Imperial Chemical Industries Fellowship, and Shell Research, Ltd., for a grant, which enabled one of us (L. B.) to take part in this work.

Ultra-violet Absorption Spectra of Proteins in Deuterium Oxide

THE absorption spectra of proteins are characterized by two absorptions in the ultra-violet region, one at 2800 and the other near 2000 Å. The former has been ascribed to the phenol[1,2], indole[3] and phenyl groups[4] of tyrosine, tryptophan and phenylalanine. The other absorption at 2000 Å. may be attributed to peptide bonds[5]. Since the absorption at 2800 Å. is due to the chromophoric groups of aromatic amino-acids, this absorption is absent in proteins, such as clupein, which do not contain aromatic amino-acid, and they have only one absorption near 2000 Å.

The contribution of aliphatic amino-acid to the ultra-violet absorption spectrum of protein solutions has not been thoroughly investigated because they do not show conspicuous absorption, except that near 2000 Å. which may be due to the carbonyl group in the COOH group[5,6].

The purpose of this work was to study the ultra-violet absorption of proteins in deuterium oxide as well as in water and to examine whether the deuteration of proteins gives rise to a change in the absorption spectrum in this wave-length region. The absorption spectra of cytochrome *c* and myoglobin, which were purified from horse heart muscle, and also ovalbumin and clupein sulphate are illustrated in the figures. According to Fig. 1 (1), cytochrome *c* has distinct absorption in deuterium oxide at 2650 Å. while it is absent in water. Although the absorption at 2800 Å. is almost hidden behind that at 2650 Å., there is still a shoulder at 2800 Å. which indicates that the electronic transition of chromophoric groups of aromatic amino-acids is not affected by deuteration and that the unknown absorption might arise from entirely different electronic transition. As is obvious from Fig. 1 (2), ovalbumin has a double-peaked absorption curve in deuterium oxide, one maximum at 2650 and the other at 2800 Å. Distinct separation of both absorptions indicates more clearly that they have different origins. Myoglobin (Fig. 1 (3)) also shows absorption at 2650 Å. in deuterium oxide, however, to a lesser extent.

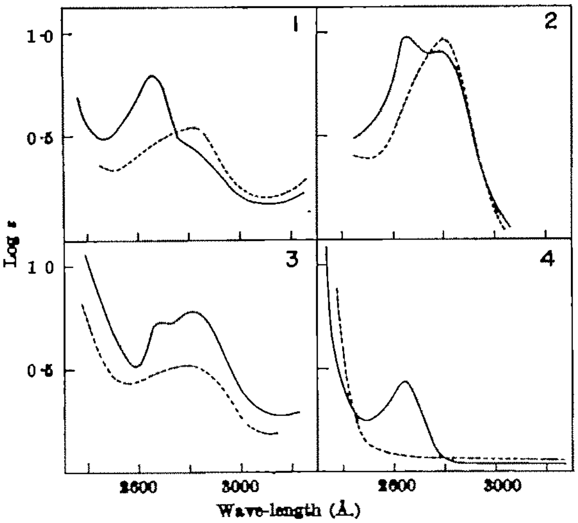

Fig. 1. Ultra-violet absorption spectra of protein solutions in deuterium oxide and water. 1, Cytochrome *c*; 2, ovalbumin; 3, myoglobin; 4, clupein, respectively. The ordinates show the relative absorption coefficients

Clupein is a protein which consists only of aliphatic amino-acids[7]. Accordingly the absorption at 2800 Å. which is characteristic of aromatic amino-acids is absent in this protein, as is shown in Fig. 1 (4) (broken line). However, this protein also shows absorption at 2650 Å. when it is dissolved in deuterium oxide, as is indicated by the solid line of Fig. 1 (4). This may be the evidence that the absorption at 2650 Å. in deuterium oxide has nothing to do with the electronic excitation of chromophores of aromatic amino-acids.

Further analyses with peptides indicate that the absorption cannot be attributed to the deuteration of the peptide bond and that it arises from the constituent simple amino-acids. Measurements with amino-acids revealed that valine, norvaline, aspartic acid, leucine, glycine and histidine showed strong absorption at 2650 Å. in deuterium oxide, but glutamic acid, alanine, aminobutyric acid and arginine and cystine did not show well-defined absorption. Measurement of tyrosine was obscured by the presence of strong absorption at 2750 Å., and I could not observe the appearance of the absorption at 2650 Å. These results indicate that some of the aliphatic amino-acids make a major contribution to the absorption of protein at 2650 Å. in deuterium oxide, rather than aromatic amino-acid, a phenomenon which has not been observed in water.

Although I have not been able to attribute this absorption to the electronic configuration of particular groups it is not likely to be due to the deuteration of dissociable groups, such as COOH, CONH or NH_2, which are capable of exchanging a hydrogen atom with deuterium atom very quickly, but may be due to the partial deuteration of non-polar groups such as hydrocarbon in α or β positions.

I am indebted to Dr. H. Tamiya for his continuous encouragement.

Structure of the Antibiotics *PA*114*B*-1 and *PA*114*B*-3

WE wish to report the partial structures of *PA*114*B*-1 and *PA*114*B*-3, members of the *PA*114 group of synergistic antibiotics obtained from a strain of *Streptomyces*[1]. Other reported synergistic antibiotic groups include streptogramin[2], staphylomycin[3], antibiotic *E*129[4], and mikamycin[5]. Bioautographic comparisons by us[6] and others[4,5] have indicated identities and close similarities between various members of the groups. Table 1 summarizes these comparisons and embodies a proposed universal system of designations.

Table 1. CLASSIFICATION OF SYNERGISTIC ANTIBIOTICS

Type	Specific compound	Synonyms
A	*A*1	*PA*114*A*-1 *E*129 Factor *A* Mikamycin *A* Streptogramin, main component Staphylomycin *MI*
	*A*2	Staphylomycin *MII*
B	*B*1	*PA*114*B*-1 *E*129 Factor *B* Mikamycin *B*
	*B*2	Staphylomycin *S*
	*B*3	*PA*114*B*-3
	Uncertain	Streptogramin, minor component

Antibiotics of the *A* group are neutral compounds giving a green ferric chloride test and a red colour with Ehrlich's reagent. The *B* antibiotics behave as weak acids, are negative to Ehrlich's reagent, and give a red ferric chloride test. One *A* antibiotic plus one *B* antibiotic constitute a synergistic pair having an antibacterial potency much higher than that of either component measured alone.

The characteristic properties of *PA*114*B*-1 and *PA*114*B*-3 clearly differentiate these antibiotics from staphylomycin factor *S* (Table 2).

Sealed-tube hydrolysis of *PA*114*B*-1 with 6 *N* hydrochloric acid at 120° was followed by two-dimensional chromatography. Butanol/acetic acid/water (5 : 1 : 4) and butanol/water/methylethyl ketone/diethylamine (10 : 10 : 5 : 1) gave the best separation of components. One ferric chloride-positive and seven ninhydrin-positive spots were observed. Displacement chromatography of a hydrolysate on 'Dowex 50' (partial separation) and quantitative paper chromatography using the butanol/acetic acid/water system was followed by aqueous elution. Vigorous hydrolysis (3 days, 120°) indicated that none of the compounds was a peptide. The following components were identified on the basis of R_F values, ninhydrin colours, specific rotations, and ultra-violet and infra-red spectra: L-threonine (Thr), L-phenylglycine (PhGly), L-proline (Pro), sarcosine (Sar), and D-α-aminobutyric acid (But). The optical configurations were confirmed by chromatography of a hydrolysate treated with D-amino-acid oxidase; only the spot corresponding to α-aminobutyric acid was lost.

From the initial aqueous wash of the 'Dowex 50' column chromatography an acidic component was isolated and identified as 3-hydroxy-picolinic acid (HyPic) on the basis of spectra and mixed melting point with an authentic sample.

Two additional ninhydrin-positive components were isolated from the paper chromatograms. Their characteristics are unlike those of any previously reported compounds. One of these unique amino-acids exhibited a yellow ninhydrin colour, a negative isatin test, and was displaced early from the 'Dowex 50' column. It had no characteristic ultra-violet absorption; analysis indicated no C-methyl, N-methyl, or alkoxyl. The properties are consistent with 5-hydroxymethylhydroxyproline-type compound (HMHyPro). Calculated for $C_6H_{11}O_4N$: C, 44·71; H, 6·88; N, 8·69; found: C, 44·98; H, 6·99; N, 8·58.

The second unique component gave a typical purple ninhydrin colour and exhibited ultra-violet and infra-red spectra indicative of an aromatic (dimethyl) amino-derivative of an α-amino-acid. These properties, together with elemental and group analyses, indicate a dimethylamino (methyl) phenylalanine-type structure (DMAMPhe). Direct concentration of an acid hydrolysate of *PA*114*B*-1 led to the isolation of this amino-acid as its dihydrochloride; m.p. 207°, $[\alpha]_D + 33°$. Calc. for $C_{11}H_{18}N_2O_2Cl_2$: C, 48·82; H, 6·83; N, 9·49; Cl, 24·02, C-CH_3(1), 5·0; N-CH_3(2), 19·7; found: C, 48·80; H, 6·89; N, 9·41; Cl, 22·93; C-CH_3, 1·52; N-CH_3, 20·18.

Treatment of *PA*114*B*-1 with 0·1 *N* sodium hydroxide for 30 min. at 25° and extraction at *p*H 3 with chloroform led to the isolation of a dibasic acid. Complete acid hydrolysis indicated that it contained all the components of *PA*114*B*-1. Hydrazinolysis of this new acid indicated that phenylglycine was C-terminal; *PA*114*B*-1 contains no C-terminal amino-

Table 2. PROPERTIES OF *PA*114*B*-1, *PA*114*B*-3 AND STAPHYLOMYCIN *S*

	*PA*114*B*-1	*PA*114*B*-3	Staphylomycin factor *S*

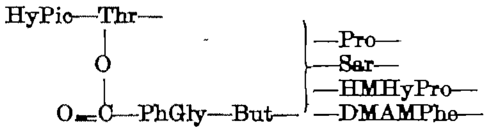
Optical activity, $[\alpha]_D^{25°}$	−59·7°	−37·2°	−28·0°
Elemental analysis C	62·07	62·77	62·80
H	6·21	6·52	6·57
N	12·77	12·61	11·46
Ultra-violet maxima (MeOH)	260 mμ (*E*(1%, 1 cm.) = 217) 305 mμ (*E*(1%, 1 cm.) = 105)	258 mμ (*E*(1%, 1 cm.) = 204) 305 mμ (*E*(1%, 1 cm.) = 95)	207 mμ (*E*(1%, 1 cm.) = 590) 304 mμ (*E*(1%, 1 cm.) = 86)
Neutral equivalent	1,000	1,070	790
pKa (MeOH)	8·5		9·0

acid. The generation of a terminal group by mild alkaline hydrolysis indicated the presence of a peptide chain closed by means of a lactone linkage—the carboxyl of phenylglycine to the hydroxyl of one of the hydroxyamino-acids. The similarity between *PA*114*B*-1 and staphylomycin factor *S* (ref. 7) makes a phenylglycine to threonine linkage, as in the latter, probable. Hydroxypicolinic acid, being incapable of forming a peptide via the nitrogen, must be N-terminal.

Partial hydrolysis of *PA*114*B*-1 (1 *N* hydrochloric acid, 37°, 1 week) and paper chromatography led to the isolation of two fluorescent peptides. After complete hydrolysis and two-dimensional chromatography on the systems described above, one of these peptides was found to have all the components of *PA*114*B*-1 except phenylglycine, confirming its C-terminal nature. The other peptide lacked only phenylglycine and α-aminobutyric acid.

At this stage we postulate the structure of *PA*114*B*-1 as:



This compares favourably with the analysis of Table 2 (calc. for $C_{48}H_{61}N_9O_{12}$: C, 60·33 ; H, 6·60 ; N, 13·11).

*PA*114*B*-3[6], a minor antibiotic of the *PA*114 complex, contains all the components of *PA*114*B*-1 except sarcosine. A new component (negative ninhydrin and ferric chloride tests) is also present ; a positive *p*-nitrobenzoyl chloride test[8] indicates that it is probably an N-methyl amino-acid.

Work on the structures of *PA*114*B*-1 and *PA*114*B*-3 are continuing.

Presence of Immunologically Active Fragments after Proteolytic Degradation of Human γ-Globulin

ACCORDING to Lapresle, Kaminski and Tanner[1], degradation of human serum albumin with trypsin or chymotrypsin yields several components with retained ability to give precipitation reactions with anti-human albumin antibodies. One of these components has been isolated by column electrophoresis in an agar medium and partially characterized by ultracentrifugation[2]. Porter[3] isolated and characterized a similar component after chymotryptic hydrolysis of bovine serum albumin. After degradation of rabbit γ-globulin with papain, Porter also isolated a component showing inhibitory properties when added to a rabbit γ-globulin–anti-γ-globulin system[4].

We have carried out immunological analyses of human γ-globulin after degradation with trypsin and chymotrypsin, respectively. Immunologically pure γ-globulin (as shown with anti-human plasma sera in immune electrophoresis), supplied by AB Kabi, Sweden, was used. Amounts of 0·1–1·0 gm. γ-globulin were hydrolysed at *p*H 8·2 and 25° C. with commercial preparations of crystalline enzymes, using enzyme/substrate ratios of 1 : 50. After 24 hr. the reaction was interrupted by the addition of diisopropyl fluorophosphate[5]. The hydrolysates were analysed by means of immune electrophoresis[6].

The results of these analyses are shown in Fig. 1. After tryptic hydrolysis, the γ-globulin gave rise to two crossing lines when analysed with anti-γ-globulin immune sera (Behringwerke, Germany). The chymotryptic hydrolysate showed by similar analysis a dense precipitate which resembled the regular γ-globulin line. In addition two other lines

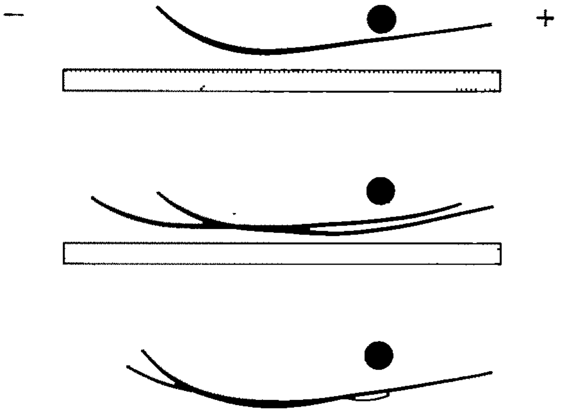

Fig. 1. Immune electrophoresis of human γ-globulin (top basin), γ-globulin degraded by trypsin (middle basin) and γ-globulin degraded by chymotrypsin (lower basin). Immune serum: anti-human γ-globulin

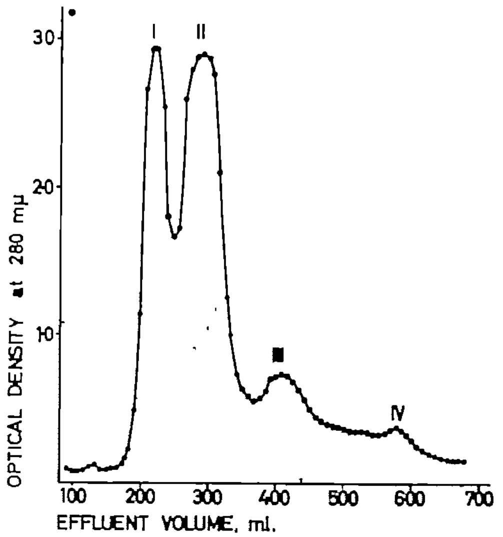

Fig. 2. Gel filtration of a tryptic hydrolysate of human γ-globulin on 'Sephadex G-75'. Eluant: 0·05 *M* sodium chloride

were formed, one farther out in the γ-globulin region and the other near the starting basin. All three lines were interconnected.

Preliminary experiments to separate the breakdown products demonstrated immunologically were carried out by the gel filtration method described by Porath and Flodin[7]. A dextran gel with a water regain of 4·9 ('Sephadex G-50', manufactured by AB Pharmacia, Sweden) was first tried. It was found, however, that more than 80 per cent of the degraded γ-globulin passed through the column without any retention. Therefore a gel with a lower degree of cross-linking was tried ('Sephadex G-75' with a water regain of 8·0). The column (4 cm. × 85 cm.) was equilibrated with 0·05 *M* sodium chloride, and the uniformity of the packing was tested by passing a hæmoglobin solution through the column. 500 mgm. of a tryptic hydrolysate of γ-globulin in 5 ml. of 0·05 *M* sodium chloride was then put on the column and eluted with a rate of flow of 20 ml. per hr. The effluent was collected in 7–8 ml. fractions, and the optical density of each fraction at 280 mμ was determined. The resulting curve is seen in Fig. 2. Immune electrophoretic analyses were carried out on fractions I–III, and the results are shown in Fig. 3. Fraction I showed one dense precipitate with its maximum mainly in the β_2- but extending into the γ-globulin region, where a confluent precipitate, farther out in the γ-globulin region, joined it. Fraction II showed two crossing lines, one with its maximum in the β-globulin region and the other with a maximum corresponding to slow-moving γ-globulin. With fraction III only a very faint precipitate was formed in the β_2-globulin region. Analogous results were obtained by gel filtration of a chymotryptic hydrolysate of γ-globulin (Cederblad, G.; Hanson, L. Å., and Johansson, B. G., unpublished work).

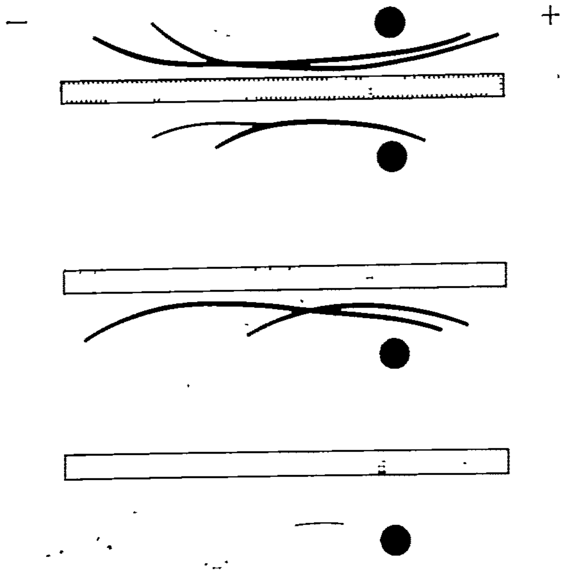

Fig. 3. Immune electrophoresis of human γ-globulin degraded by trypsin (top basin) and of fractions I, II and III obtained by gel filtration of this degraded γ-globulin. Immune serum: anti-human γ-globulin

From these results it can be concluded that normal human γ-globulin contains different antigenic groupings, with the ability to react with anti-γ-globulin antibodies. Corresponding findings concerning pathological γ-globulins have been presented by Scheidegger and Buzzi[8].

Further work on the isolation and characterization of immunologically active degradation products from immune globulins is in progress.

We are grateful to the Misses M. Wikström and A. Wallin for skilful technical assistance. The work was supported by grants from the Medical Faculty, University of Gothenburg, and the Swedish Dairies' Association.

Starch-Gel Electrophoresis of Wheat Proteins

IT has been claimed that starch-gel electrophoresis may have a higher resolving power than that of the Tiselius apparatus for serum proteins[1]. In spite of its potential value, there have been no reports in the literature of the application of this technique to the study of wheat proteins. Wheat gluten has been separated into at least six components by Jones *et al.*[2], using the Tiselius apparatus, and Zentner[3] has reported the presence of seven proteins, using continuous paper electrophoresis. The present communication describes some preliminary experiments in which starch-gel electrophoresis has been used to examine the proteins of the gluten complex of wheat.

10 gm. of wet gluten were prepared from wheat flour by hand kneading in distilled water and were dispersed in 200 ml. *N*/100 acetic acid in a high-speed

stirrer, fitted with sharp steel blades, in 5 min. After centrifuging for 30 min. at 2,000 r.p.m., the liquid was subjected to starch-gel electrophoresis. Both horizontal and vertical[4] techniques were used. Connaught starch was used, 12·2 gm. mixed with 100 ml. of an aluminium lactate buffer[3]. The sample slot (1–2 mm. wide) was filled with protein solution mixed with starch granules, but in later work the starch was omitted without affecting the quality of the patterns. Runs were normally made for 2–4 hr. at a potential gradient of 4–6 V. cm.$^{-1}$. The gels were sliced and the cut surfaces stained with naphthalene black 10*B*.

Centrifugation at 2,000 r.p.m. does not remove colloidal particles, which migrate into the gel for several mm., and tend to obscure some of the slower-moving bands. They stain strongly, but can be distinguished from a true band by the characteristic irregular appearance. Under a low-power microscope the 'band' can be seen to consist of dyed particles. When a dispersion was cleared by ultracentrifugation at 20,000*g*, the 'band' no longer appeared on electrophoresis.

Table 1

Mobility (cm.^{2} V.$^{-1}$ sec.$^{-1}$)	Intensity of band			
	Bison	Flamingo	Rescue	Witchita
2·6	*m*	?	?	*m*
3·5	*s*	*m*	?	*m*
4·2	*s*	*s*	*s*	*s*
6·4	*f*	*m*	*m*	*f*
8·3	*m*	*s*	*m*	*m*
9·2	*f*	*m*	*m*	*f*
10·2	*vf*	*f*	*f*	*f*
12·7	*vf*	*f*	*f*	*f*

vf, very faint; *m*, medium; *s*, strong; ?, partially obscured.

Table 1 gives an example of electrophoresis patterns obtained on a four-channel vertical apparatus[4] for glutens from four wheat varieties of widely differing baking characteristics (Table 2). It is interesting to note that each of the four varieties examined shows patterns of similar electrophoretic mobilities, and the patterns differ only in the distribution of intensities. It should be pointed out that the presence of eight distinct and separate bands in the electrophoresis patterns does not necessarily prove that eight different proteins are present, since some of the bands could conceivably arise as a result of complex formation.

Table 2

Wheat	Source	Type	Baking strength
Bison	U.S.A.	Hard red winter	Strong
Flamingo	England	White winter	Very weak
Rescue	U.S.A.	Hard red spring	Weak
Witchita	U.S.A.	Hard red winter	Medium

The pattern of mobilities quoted in Table 1 is typical of the results of a large number of experiments, in all of which at least eight distinct bands have been found, but variations of the order of 20 per cent in mobility are found when comparing individual runs. This is probably due principally to the difficulty in preparing gels of precisely reproducible properties. The mobilities reported here are higher than those obtained for wheat proteins by Jones *et al.*[2] at 1° C. The highest value obtained by them was 6·5 × 10^{-5} cm.^{2} V.$^{-1}$ sec.$^{-1}$. Our experiments were carried out at approximately 25° C., and the increase in conductivity, due to the use of a higher temperature, would be enough to account for the increased mobilities, since the presence of starch up to concentrations of 12·5 per cent does not significantly affect the electrical conductivity of salt solutions (Collison, R., private communication).

The work reported here demonstrates that starch-gel electrophoresis is a valuable method for investigating wheat proteins, as complete resolution of the eight bands reported was obtained. Further studies of the protein components in wheats of different origin are in hand, using this method in conjunction with column chromatography and immuno-techniques.

Thanks are expressed to Mr. E. N. Greer of the Research Association of British Flour Millers for milling the wheats used in these experiments.

Activity of Bovine Pancreatic Ribonuclease *A* in Mixed Solvent Systems

It has been shown that bovine pancreatic ribonuclease may be dissolved in organic solvents with full recovery of the activity after removal of the solvent[1]. We have found that ribonuclease *A* retains its activity in the presence of high concentrations of many organic solvents and have utilized this property for investigating its mode of action. If the solvent used is methanol then the products of the action of ribonuclease on cytidine-2′,3′-phosphate are cytidine-3′-phosphate and cytidine-3′-phosphate methyl ester as previously observed by Heppel and Whitfeld[2]. As the mole fraction of methanol is raised, methanolysis increases and hydrolysis decreases as shown in Fig. 1. This behaviour is consistent with competition between methanol and water for a site on the enzyme.

The effect of solvents on enzyme-catalysed reactions is due to many causes including shifts in *pK*'s of buffers, substrate and protein as well as direct effects on the binding and catalysis. Thus solvent effects have contributed little to our understanding of enzyme catalysis. However, for ribonuclease it is possible to observe simultaneously the effect of addition of solvent on methanolysis and hydrolysis. This has been achieved by keeping a constant ratio of water : methanol while varying the concentration of another, inert, organic solvent (dioxane, formamide and dimethyl formamide). Under these conditions the solvent will have widespread effects but those involving the cyclic phosphate probably do not influence the relative rates of hydrolysis and methanolysis. Thus any changes in the relative rates which are observed may be attributed to the effects of the solvent on the interaction of water or alcohol with the protein. In Fig. 2 are shown the effects of dioxane and formamide on the ratio of the initial rates of esterification and hydrolysis. While formamide has little effect on this ratio, hydrolysis is very much favoured by increasing amounts of dioxane. This effect is not due to alteration of *pK*'s since the ratio esterification : hydrolysis was found to be substantially independent of *p*H when this was varied over a range covering any likely *pK* change. It is

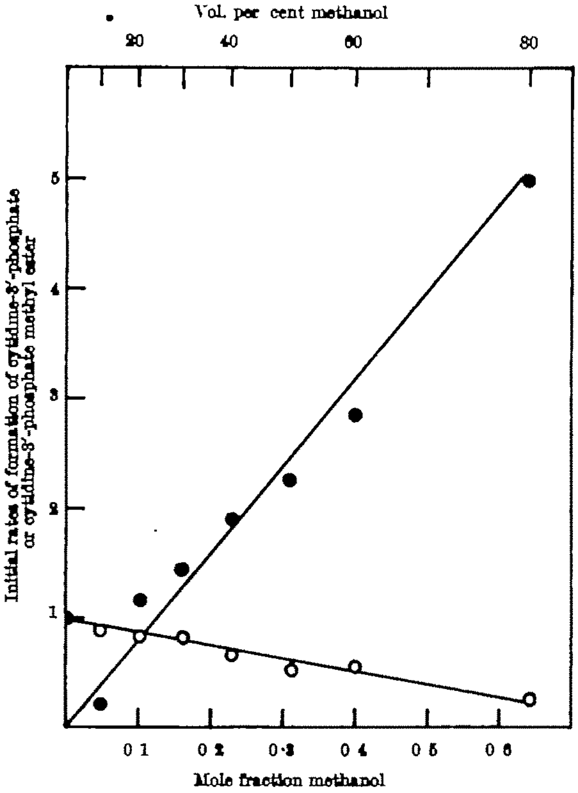

Fig. 1. The effect of methanol on the initial rates of formation of cytidine-3'-phosphate methyl ester (●) and cytidine-3'-phosphate (○). Rates are relative to hydrolysis of cytidine-2',3'-phosphate in absence of methanol. Cytidine-2',3'-phosphate, 0·05 *M* in citrate buffer at *p*H 6·9. Temperature, 25° C.

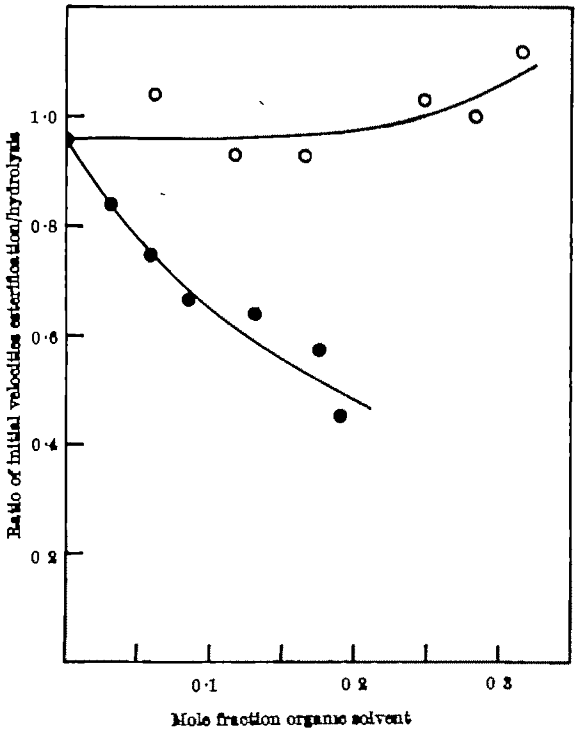

Fig. 2. The effect of formamide (○) and dioxane (●) on the ratio of the initial velocity of esterification to the initial velocity of hydrolysis of cytidine-2',3'-phosphate. Ratio water : methanol constant and equal 3 · 1 v/v

evident that there is a site on the enzyme surface which binds either water or methanol. The superiority of methanol as an attacking reagent (Fig. 1) and the effect of dioxane suggest that there is a Van der Waals interaction between methanol and the protein. Dioxane favours hydrolysis relative to methanolysis by interfering with the Van der Waals interaction.

It can be seen that considerable information can be obtained by measuring the activity of enzymes in mixed solvent systems. By investigating the effect of organic solvents on the *p*H activity curves using buffers of both types of charge, it should be possible to determine the type of charge of the ionizing groups controlling the enzyme activity.

Action of Tetrakis(Hydroxymethyl)Phosphonium Chloride on Wool

In an investigation of the action of tetrakis(hydroxymethyl)phosphonium chloride (THPC) on wool the following interesting observations have been made.

When wool treated with tetrakis(hydroxymethyl)phosphonium chloride is dyed together with a sample of untreated wool with acid or premetallized dyes, the treated wool absorbs much more dye than the untreated. Uptake of the basic dye methylene blue is, however, less for the treated than for the untreated wool. The addition of tetrakis(hydroxymethyl)phosphonium chloride to the dye liquor greatly accelerates the rate of dye absorption.

When wool fibres, stretched 40 per cent, are boiled for various times in tetrakis(hydroxymethyl)phosphonium chloride solution (2 per cent) and afterwards relaxed for 1 hr. in boiling water, the results shown in Fig. 1 are obtained. It is evident that the amount of

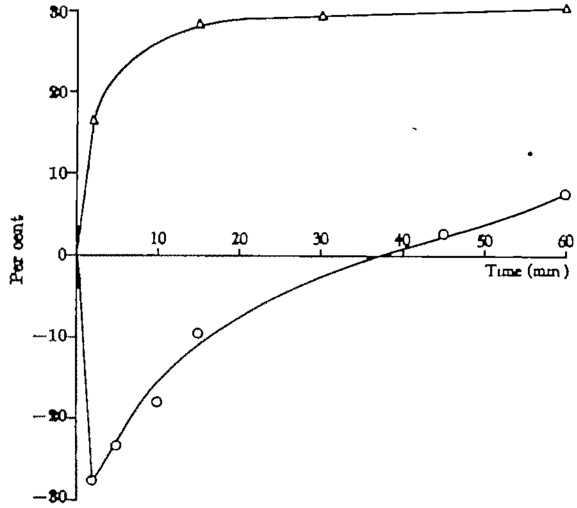

Fig. 1. Variation of set with time of treatment at the boiling point. ○, In water; △, in THPC

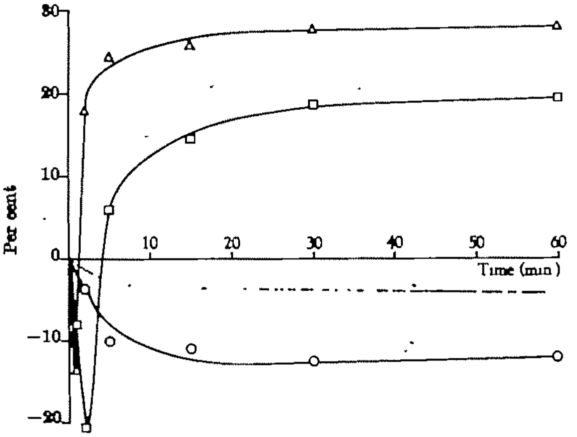

Fig. 2. Variation of set with time of treatment at the boiling point. ....., Deaminated, iodinated and potassium cyanide-treated fibres in water; △, iodinated fibres in THPO; □, deaminated fibres in THPO; ○, potassium cyanide-treated fibres in THPO

set retained by the fibres after they have been afterwards boiled freely is much greater than after a similar treatment of stretched fibres in boiling water. The effect of tetrakis(hydroxymethyl)phosphonium chloride depends on the strength of the solution, but is marked even at a concentration of 0·1 per cent. In dilute solutions the supercontraction characteristic of stretched fibres in boiling water is observed. Typical results are shown in Table 1.

Table 1

Concentration of THPO solution (per cent)	Set (+ve sign) or supercontraction (−ve sign) after relaxing the fibres, treated in the stretched state for 2 min.	120 min.
0·1	−17·8	28·6
0 5	+4·9	22·9
1·0	13 0	22·5
2 0	17·1	24·5

It is not possible to set stretched fibres which have been previously iodinated or deaminated in boiling water, but these materials are readily set in a solution of tetrakis(hydroxymethyl)phosphonium chloride (2 per cent). It is not, however, possible to set stretched fibres which have been previously treated with potassium cyanide, either in water or tetrakis (hydroxymethyl)phosphonium chloride solutions. These results are shown in Fig. 2.

When slack fibres are boiled in a solution of tetrakis(hydroxymethyl)phosphonium chloride (1 per cent) for 1½ min. at pH 7, supercontraction occurs to the extent of 38 per cent.

The reaction of tetrakis(hydroxymethyl)phosphonium chloride with wool is no doubt complex; but at present it is considered to involve reduction of the disulphide bond as the primary process, accompanied by the absorption of the phosphonium ion, thus increasing the number of positive sites in the fibre. Work on this topic is proceeding and will be reported in full elsewhere.

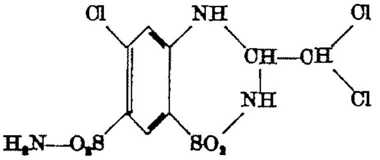
PHYSIOLOGY

A Potent New Benzothiadiazine Diuretic

Since the discovery of chlorothiazide by Beyer *et al.*[1], a number of chemically related compounds have been shown to possess similar natriuretic and chloruretic actions[2-4]. Some of these agents, notably 3,4-dihydrochlorothiazide and its derivatives, differ from chlorothiazide primarily in a greater milligram potency, which may be associated with a longer duration of action[5]. These agents also inhibit carbonic anhydrase to a lesser extent than the unsaturated analogues, resulting in a lower urinary pH and generally a greater chloruretic response[5,6].

In an effort to determine how further structural modifications of the chlorothiazide nucleus might alter the renal actions, we have undertaken an investigation of derivatives substituted in the 3 position of the dihydro analogue[7]. This is a preliminary report of pharmacological studies on one of these compounds, trichlormethiazide (*NAQUA*^{TM} is the Schering brand of trichlormethiazide), which has been characterized by marked diuretic activity at very low doses. The chemical formula of this agent is as follows:



3-dichloromethyl-6-chloro-7-sulphamyl-3,4-dihydro-1,2,4-benzothiadiazine-1,1-dioxide (trichlormethiazide).

The effect of trichlormethiazide on urine and electrolyte excretion was studied in anæsthetized dogs in which the ureters were cannulated and total urine was collected every 5 min. Urine samples were analysed for sodium, potassium and chloride. Typical results of intravenous administration of 1·0 µgm./kgm. are presented in Table 1.

Table 1. Effect of Trichlormethiazide on Urine Output and Electrolyte Excretion in an Anæsthetized Dog

Time (min.)	Urine (ml./min.)	Sodium	Potassium	Chloride
		Microequivalents per min.		
−15	0 26	98	43	68
−10	0·26	101	39	65
−5	0·24	100	31	62
0	1·0 µgm./kgm. trichlormethiazide (intravenous)			
5	0·28	112	32	68
10	0·32	136	34	85
15	0 34	134	30	98
20	0·32	128	30	96
25	0·30	122	30	88
30	0·28	126	31	82
35	0·24	97	25	67

These results demonstrate that a significant natriuretic and chloruretic response can be elicited at doses as low as 1·0 µgm./kgm. and that the sodium and chloride increases are equimolar. Potassium excretion increased slightly but considerably less than sodium and chloride. The maximum natriuretic response occurred approximately 10 min. after administration. Duration of action was 30 min.

The relative activities of trichlormethiazide in terms of chlorothiazide, and trichlormethiazide in terms of 3,4-dihydrochlorothiazide, by the oral route have been determined in unanæsthetized dogs using a modified cross-over design (32 animals for each assay). Dose-levels (2) and compounds (2) were both crossed over on two experimental days set one week apart. The doses were selected on the basis of previous experimental data to elicit approximately the same natriuretic response. Urine and sodium excretion-rates were determined for a 5-hr. period after treatment. Relative activities of trichlormethiazide were obtained by comparing the dose-response curves and analysing the results by statistical methods. The results are summarized in Table 2.

Table 2. COMPARATIVE ACTIVITY OF THREE THIAZIDE DIURETICS ON URINE OUTPUT AND SODIUM EXCRETION IN DOGS

Compound	Dose µgm./kgm.	Urine output ml./5 hr.	Urine output Relative activity	Sodium excretion m.eq./5 hr.	Sodium excretion Relative activity

TCM	90	79	(7·1–9·4)*	19·6	(6·5–34·0)*

* 95 per cent confidence limits.

† Confidence limits could not be calculated since analysis showed significant non-parallelism between curves at P 0·01.

On a dose basis, trichlormethiazide was found to be 72·0 times more active than chlorothiazide and 13·6 times more active than 3,4-dihydrochlorothiazide in promoting the excretion of sodium. Potency values for urine output were 58·9 and 7·9, respectively. Average urine output in the same animals, untreated, was found to be 30–40 ml./5 hr. while control sodium excretion averaged 4–8 m.equiv./5 hr. These findings suggest that the minimally effective oral dose of trichlormethiazide is less than 15 µgm./kgm., and that this agent, like chlorothiazide and 3,4-dihydrochlorothiazide, is well absorbed through the gastrointestinal tract.

Effect of Cocaine on the Disposition of Noradrenaline labelled with Tritium

COCAINE potentiates the responses of sympathetically innervated organs to adrenaline, noradrenaline and sympathetic nerve stimulation, and several explanations have been offered for this. Cannon and Rosenblueth[1] suggested that cocaine might act by preventing the destruction of injected adrenaline, or of transmitter substance released from adrenergic nerves, and Torda[2] and Trendelenburg[3] obtained evidence in support of this hypothesis. Macmillan[4] suggested that cocaine might prevent the uptake of catecholamines into tissue stores, and block their release from these stores, but his evidence was only indirect.

O-methylation is a major route for the inactivation of circulating catecholamines[5], and, more recently, binding by many tissues has been shown to be important for the inactivation of circulating adrenaline[6] and noradrenaline[7]. This communication describes the influence of cocaine on the uptake into tissues of noradrenaline labelled with tritium, and the formation of ^{3}H-normetanephrine by O-methylation.

Male cats (1·7–3·6 kgm.) were anæsthetized with pentobarbitone sodium (35 mgm./kgm.) intraperitoneally and a tracheostomy performed. The right femoral artery was cannulated for recording the blood-pressure and the left femoral artery for the withdrawal of blood samples. Cocaine (5 mgm./kgm.), dissolved in 5 ml. 0·9 per cent (w/v) sodium chloride solution, was injected intravenously over a period of 5–10 min. When the blood-pressure had returned to a steady level, *dl*-β-^{3}H-noradrenaline (1·72 mc./mgm.) was injected intravenously (dose, 25 µgm./kgm.) within 5–10 sec. Blood samples were withdrawn periodically and the animals were decapitated 1 hr. after the injection of noradrenaline. Adrenal glands, heart, liver, abdominal wall muscle and spleen were removed immediately, homogenized and analysed for ^{3}H-noradrenaline and ^{3}H-normetanephrine[8].

Table 1. EFFECT OF COCAINE ON THE TISSUE CONTENT OF ^{3}H-NORADRENALINE AND ^{3}H-NORMETANEPHRINE

Results are expressed in mµgm. ^{3}H-noradrenaline or ^{3}H-normetanephrine per gm. of tissue (mean value ± *S.E.*), and were obtained with seven untreated and four cocaine-treated cats (for details of dosage see text). Cats were injected intravenously with ^{3}H-noradrenaline (25 µgm./kgm.)

Tissue	^{3}H-Noradrenaline		^{3}H-Normetanephrine	
	Untreated	Cocaine-treated	Untreated	Cocaine-treated
Adrenal gland	121 ± 17	26 ± 9·0	9·0 ± 1·2	5·5 ± 0·5
Heart	165 ± 20	29 ± 5·8	16·4 ± 3·2	5·2 ± 0·4
Spleen	151 ± 21	22·5 ± 1·9	17 ± 1·9	7·1 ± 0·5
Liver	18·7 ± 3·9	8·0 ± 0·7	8·0 ± 1·1	6·3 ± 1·2
Skeletal muscle	4·6 ± 0·7	3·0 ± 0·5	5·2 ± 1·1	8·1 ± 0·7

The effect of cocaine on the concentrations of ^{3}H-noradrenaline and ^{3}H-normetanephrine in tissues is shown in Table 1. Adrenal glands, heart and spleen are three tissues in which uptake and retention of injected noradrenaline has been shown to be greatest[7]; in these organs administration of cocaine has resulted in a marked reduction in their content of ^{3}H-noradrenaline. The quantity of ^{3}H-noradrenaline in liver and skeletal muscle 1 hr. after the injection was also reduced, but to a smaller extent. The effect of cocaine on the tissue-levels of ^{3}H-normetanephrine was less marked; reductions were observed in heart and spleen and an elevation in skeletal muscle. Because of its bulk, muscle accounts for most of the ^{3}H-noradrenaline and ^{3}H-normetanephrine remaining in the animals at the end of the experiments.

Table 2 shows the plasma-levels of ^{3}H-noradrenaline and ^{3}H-normetanephrine at various times after the injection of ^{3}H-noradrenaline. In the cocaine-treated animals the level of ^{3}H-noradrenaline exceeded the control-levels during the first 3 min. after the injection, confirming the observations of Trendelenburg[3], but in later blood samples there was no significant difference between the two groups.

These experiments show that cocaine markedly reduces the uptake of circulating noradrenaline into

Table 2. INFLUENCE OF COCAINE ON PLASMA LEVELS OF ^{3}H-NORADRENALINE AND ^{3}H-NORMETANEPHRINE

Results are expressed in mμgm. ^{3}H-noradrenaline or ^{3}H-normetanephrine per ml. of plasma (mean value ± *S.E.*)

Time after injection (min.)	^{3}H-Noradrenaline		^{3}H-Normetanephrine	
	Untreated	Cocaine-treated	Untreated	Cocaine-treated
1	80·3 ± 9·5	212 ± 19	3·9 ± 0·5	5·5 ± 0·7
2	49·3 ± 5·8	89·5 ± 9·0	5·7 ± 1·0	6·4 ± 0·9
3	31·1 ± 3·1	51·7 ± 7·5	5·6 ± 0·7	8·4 ± 1·1
5	21·5 ± 1·7	25·1 ± 2·8	5·5 ± 0·8	8·3 ± 1·2
10	13·8 ± 1·3	13·3 ± 0·9	3·6 ± 0·5	4·8 ± 0·6
30	8·5 ± 1·4	7·3 ± 0·5	1·5 ± 0·1	1·9 ± 0·1
60	5·4 ± 0·5	3·9 ± 0·4	1·1 ± 0·2	0·8 ± 0·05

certain tissues, presumably by interfering with binding of the hormone. This interference with the uptake raises the amount of circulating catecholamine, and this is reflected in the increased plasma noradrenaline-levels observed in the early stages after an intravenous injection. Noradrenaline therefore exists in a free and active state for a longer period than in untreated animals, and these observations may be sufficient to explain the effect of cocaine in increasing the sensitivity of sympathetically innervated organs to circulating catecholamines.

It is unlikely that cocaine is acting by interfering with the enzymic inactivation of injected noradrenaline, since we have found that it does not inhibit O-methyl transferase *in vitro*. Furthermore (Table 1), cocaine has had little effect on the content of ^{3}H-noradrenaline, and no significant effect on the concentration of ^{3}H-normetanephrine in the liver, which is the organ having the highest concentration of catechol-O-methyl transferase[9].

We have found that reserpine also reduces the tissue content of ^{3}H-noradrenaline, and elevates the plasma-levels (unpublished observations). Both reserpine[10] and cocaine[1] cause supersensitivity of sympathetically innervated organs, but reserpine releases catecholamines from tissue stores[11], whereas cocaine prevents both their release[10,12] and uptake in the tissues. Although acting by different mechanisms, both drugs produce a common end-result, that is, lower tissue concentration of administered catecholamine, elevated plasma-levels of the free hormone, and consequently supersensitivity.

Effect of Trypan Blue on Rat Embryos

THE teratogenic effect of trypan blue in pregnant rats has been well established[1-3]. The dye appears to be most active when injected at 8½ days of pregnancy and gives rise to a variety of abnormalities involving almost all the systems of the embryo. Of a number of chemically related azo dyes tested, trypan blue was found to be the most active teratogenic agent in rats[4] and it has also been shown to act as a teratogen in other rodents[5-7] and in chicks[8]. Three main hypotheses explaining its action have been proposed. The first assumed that a part, at least, of the dye enters the blastocyst and acts directly on the embryonic cells[9]; the second postulates a 'clogging' of the yolk sac epithelium with the large dye molecules, thus inhibiting the transfer of essential substances to the conceptus; the third suggests maternal metabolic changes resulting in the formation of substances which are responsible for the fœtal malformations.

During our own preliminary investigations into the action of trypan blue it was found that the commercial sample used was grossly impure.

A brief survey (Table 1) of the purity of various other commercial samples showed that the chief impurity was sodium chloride, which is used for the salting out of the dye during its manufacture. The actual amount of the azo dye in the samples varied from 19·8 to 85·6 per cent, and for this reason it is difficult to compare dosage-levels and to assess the results of previous workers who have used commercial sources of the dye.

Paper chromatography of the dye samples has revealed in all cases a number of chromogenic impurities, the main one being red in colour. The ratio of red impurity : trypan blue, in the various dye samples, has been determined spectrophotometrically after chromatographic separation (Table 1, col. 4). This impurity has been previously noted in trypan blue[10,11] and a similar red impurity has been found in Evans's blue (*T* 1824) (ref. 12). The latter dye is also to some extent teratogenic[4].

The main red impurity ($\lambda_{max.}$ 540 mμ in *N* hydrochloric acid) was separated from the first mother liquor obtained after the recrystallization of crude trypan blue (Grübler). A 'Solkaflock' cellulose column was used with water as the eluting agent. The mother liquor was de-ionized in a Wood's electro-dialyser[13] before being applied to the column, and the separated red fraction was dried *in vacuo* and dissolved in water to give a 0·5 per cent w/v solution. The red material, which is of unknown structure, diffused slowly through a 'Cellophane' membrane and when injected into rats was quickly excreted in the urine. It therefore seems feasible to assume that the red impurity of trypan blue can enter the blastocyst.

Recrystallization of trypan blue (Grubler) twice from hot water gave a blue dye ($\lambda_{max.}$ 590 mμ in *N* hydrochloric acid) which showed negligible chloride content and only a trace of the red impurity. Further purification of this material was not possible at this time due to the restricted supply of the sample available and the large losses consequent on recrystallization. The recrystallized trypan blue did not diffuse through a 'Cellophane' membrane, and when injected into rats it was not excreted in the urine; it was dried *in vacuo* and dissolved in water to give a 1 per cent w/v solution.

Table 2

Substance tested	No. of rats used	Total implantations	Total resorptions	Resorptions (per cent)	External abnormalities in survivors Normal	 Abnormal
M.R.C. hooded rats						
Control (uninjected)	14	148	10	6·7	138	0
1 per cent trypan blue (Grubler)	11	117	36	30·7	80	1
1 per cent recrystallized trypan blue	12	144	18	12·5	126	3
1 per cent mother liquor	14	148	46	31·8	102	2
0·5 per cent red impurity	19	224	47	20·9	176	1
Wistar rats						
Control (uninjected)	4	33	2	6·0	31	0
1 per cent crude trypan blue	7	48	27	56·2	9	12

The mother liquor from the first recrystallization of trypan blue (Grubler) was also dried *in vacuo* and dissolved in water to give a 1 per cent w/v solution. This solution was rich in the red impurity, the ratio of the respective $E_{max.}$ values (cf. Table 1) of the red and blue components being 0·95 compared with 0·16 in crude trypan blue (Grübler).

For testing the effect of trypan blue M.R.C. hooded rats of our laboratory strain were used. Rats in œstrous (determined by the vaginal smear) were mated overnight and pregnancy was timed from midnight if the morning smear showed spermatozoa. At 8½ days of pregnancy the rats were injected subcutaneously with 1 ml. of 1 per cent commercial typan blue (Grübler) or solutions of fractions derived from it (*vide supra*) and killed at 20½ days. The number of fœtuses and resorption sites was noted. Fœtuses were removed, fixed in formalin and examined for external malformations. A series of control animals remained uninjected.

Table 2 shows the results obtained.

The demonstration that recrystallized trypan blue gave a resorption-rate (12·5 per cent) that was not significantly different ($0·20 > P > 0·10$) from the control group (6·7 per cent) suggested that it was the impurities in the crude samples of the dye which were responsible for its high resorption-rate (30·7 per cent). This appeared to be borne out when it was shown that the mother liquor containing these impurities caused resorption (31·0 per cent) at the same rate ($0·95 > P > 0·90$) as the crude material.

Since the control animals were uninjected, injection trauma was considered as a factor responsible for the resorptions in the experimental series. This consideration could be ruled out, since the resorption-rates given by the series injected with recrystallized trypan blue and the controls do not differ significantly ($0·20 > P > 0·10$).

Since the main impurity in crude trypan blue (Grübler), apart from sodium chloride, was the red chromogenic material, it was considered that this compound might be the causative resorptive agent. Tests with the impurity showed that the resorption-rate (20·9 per cent) although significantly ($P < 0·01$) higher than that of the controls fell between that of recrystallized trypan blue and the crude trypan blue (Grubler) (Table 2).

All fractions—including the pure red fraction which contained no trypan blue at all—were found to cause gross abnormalities, but χ^2 tests of significance failed to show differences in abnormality-rates between the experimental groups due to the small number of externally malformed fœtuses. All fœtuses are now being dissected to demonstrate cardio-vascular abnormalities.

Although the activity of the recrystallized trypan blue cannot be considered to have been disproved, it would appear that the red impurity is more active so far as fœtal resorptions are concerned. An attractive explanation of why the mother liquor was more active than the red impurity itself is that the red compound, being diffusible, is rapidly excreted when injected alone and may not be present at an optimal concentration at the correct period of fœtal development. When, as in the mother liquor or crude trypan blue, the red compound and trypan blue are injected together, the excretion of the red compound may be delayed by partial 'blocking' of the reticulo-endothelial system by trypan blue. Another point that should be mentioned is that the red fraction, as eluted from the cellulose column, contained only the main impurity and that other, possibly more active, compounds which were present in the crude trypan blue or the mother liquor may have been left on the column. Finally, it should be pointed out that the amount of total dye injected into the group of rats receiving the red impurity was only a half that received by the other groups.

Recently, a Wistar strain of rat has been subjected to the experimental treatment outlined above using 1 ml. of 1 per cent crude trypan blue (Grubler) (Table 2). Whereas there is no difference in resorption-rates between control Wistar and M.R.C. hooded rats (P about 0·8) the Wistar rats show a significantly higher ($P < 0·01$) resorption-rate (56·2 per cent) (and also a very much higher abnormality-rate among survivors) than do the M.R.C. hooded rats (30·7 per cent). Experiments with the various fractions of crude trypan blue are now being repeated on the more susceptible strain especially with the view of examining the rates of congenital malformation in the survivors.

Antileukæmic Activity of Glycyrrhetinic Acid

Recently some pharmacologically interesting activities of glycyrrhetinic acid corresponding to those observed with the adrenal cortical hormones have been shown; for example, a DOCA-like effect on sodium and potassium metabolism in normal people[1] and an anti-inflammatory activity in different animal tests[2].

It seems that the drug acts through the adrenals, because no effect on the sodium and potassium balance in adrenalectomized rats has been established.

Investigations to obtain a substance like adrenal cortical hormone by transforming the carboxyl-group of glycyrrhetinic acid in a ketol group and the 3-OH group in an oxo-group did not enhance or change the activity[4].

Experiments carried out recently by L. M. Atherden[5] have contributed to the explanation of the mode of action of glycyrrhetinic acid. This author showed that a direct effect on the steroid enzyme system inhibits the metabolism of progesterone and 11-deoxycorticosterone. In this test 11-deoxoglycyrrhetinic acid inhibits to a small extent only. This demonstrates that the 11-oxo-group is required for inhibition.

The purpose of this communication is to describe a further parallel between the activity of adrenal cortical hormones and glycyrrhetinic acid.

E. R. Heilman and E. C. Kendall[6] have shown that cortisone retards growth of malignant lymphosarcoma in mice. Similar results have been obtained by J. B. Murphy and E. Sturm[7] with adrenal cortical hormones in oil: in rats, development of the disease after inoculation with leukæmic cells has been prevented. About 50 per cent of the rats survived while the survival among controls was less than 5 per cent.

Clinical investigations have also demonstrated the effectiveness of cortisone therapy in acute leukæmia, especially in the lymphoblastic variety of acute leukæmia[8].

We have found that glycyrrhetinic acid has a similar activity on the development of transplantable Oberling–Guérin myeloma in rats: α- and β-glycyrrhetinic acid react qualitatively in the same way (Table 1, *b* and *c*); but it seems that the α-compound is more active. Also the corresponding 3-oxo-compounds (*d* and *e*) behave analogously. With the 3-oxo-20-ketolacetate (*f*) of glycyrrhetinic acid we have obtained different results with different kinds of leukæmias: with the Oberling–Guérin myeloma some activity has been noted, whereas a lymphatic tumour of the mouse (leukæmia 1210) does not seem to be sensitive to the drug. The compound 3-oxo-

Table 1. Effect of Glycyrrhetinic Acid and Derivatives on the Development of Transplantable 'Oberling–Guérin' Myeloma in Rats

Compound	Daily dose (mgm./kgm.* intraperitoneally)	No. of animals	Mortality No. of animals	Average tumour weight treated / Average tumour weight controls	Change in body-weight after 12 days Treated / Controls
(*a*) Cortisone	50	9	0	0·45	$\frac{+0}{+20}$

(*c*) 18 α-Glycyrrhetinic acid	80	25	0	0·47	$\frac{+15{\cdot}5}{+19{\cdot}8}$
(*d*) 3-Oxo-18 α-glycyrrhetinic acid	80	20	2	0·33	$\frac{+20{\cdot}2}{+18{\cdot}3}$
(*e*) 3-Oxo-18 β-glycyrrhetinic acid	80	17	2	0·46	$\frac{+12{\cdot}8}{+17{\cdot}5}$
(*f*) 3-Oxo-20-ketolacetate-18 β-glycyrrhetinic acid	50	5	0	0·42	$\frac{+17{\cdot}0}{+18{\cdot}8}$
(*g*) 11-Deoxo-18 β-glycyrrhetinic acid	100	10	0	0·88	$\frac{+17{\cdot}7}{+14{\cdot}6}$
(*h*) 3-Oxo-18 α-glycyrrhetinic-β-dimethylaminoethylester methansulphonic salt	50	10	1	0·91	$\frac{+19{\cdot}0}{+24{\cdot}5}$
(*i*) 3-Oxo-18 β-glycyrrhetinic-β-dimethylaminoethylester methansulphonic salt	50	10	4	0·94	$\frac{+8{\cdot}2}{+18{\cdot}3}$
(*k*) 3-Acid-hydrogen-succinate of α-glycyrrhetinic disodic salt	50	10	1	0·65	$\frac{+14{\cdot}40}{+23{\cdot}17}$
(*l*) 3-Acid-hydrogen-succinate of β-glycyrrhetinic disodic salt	50	10	2	0·70	$\frac{+21{\cdot}20}{+23{\cdot}17}$

* Duration of treatment: 11 days starting 24 hr. after tumour implantation.

18-α-glycyrrhetinic acid (*d*) was also active against leukæmia 1210.

A negative result was obtained with 11-deoxoglycyrrhetinic acid (*g*). In order also to carry out experiments with water-soluble compounds, which eventually could show a higher activity, we have tested the β-dimethylaminoethylester of 3-oxo-β-glycyrrhetinic acid (*i*), but it was inactive. Since the β-acid in comparison with the α-acid is much more difficult to hydrolyse[4], we have investigated also the corresponding α-acid ester (*h*): it has proved to be inactive as well. The β- and α-acid hydrogen succinates of glycyrrhetinic acid are also inactive. These 3-succinates have a high anti-inflammatory activity (R. S. H. Finney and G. F. Somers[2]).

It is of interest to note that the glycyrrhetinic compounds do not inhibit the increase in body-weight as in the case of cortisone (Table 1). We have not yet been able to establish whether this fact is in part due to retention of water.

With other tumours, for example, mouse sarcoma 180, no activity was observed with any of the listed compounds. Tumour growth was determined by weighing the localized excised tumours 12 days after subcutaneous implantation of a rat myeloma cell suspension or 8 days after transplantation of the mouse sarcoma 180. Adult Wistar rats or stock albino mice of both sexes were used throughout the experiments.

We are indebted to the Cancer Chemotherapy National Service Center, National Institutes of Health, Bethesda 14, Maryland, for carrying out the determinations on 1210 leukæmia-bearing mice.

Protective Effect of Cysteine against Retinal Degeneration induced by Iodate and by Iodoacetate

ACUTE degenerative lesions of the neuro-epithelium and of the pigment layer of the retina can be readily induced in the rabbit by a single intravenous injection of five different agents, namely, sodium iodate[1], sodium iodoacetate[2], dithizone[3], the primary phenoxyalkanes[4] and sodium fluoride[5]. To be effective, sodium iodoacetate and sodium fluoride have to be given in sub-lethal doses, and only some 66 per cent and some 20 per cent, respectively, of animals treated with these agents show ophthalmoscopic lesions. With the remaining substances, well-tolerated doses produce retinal lesions in all rabbits treated. The severity of the lesion produced by an agent varies from animal to animal, so that it is difficult to be sure whether there is a fundamental difference between the reactions produced by these five agents; however, dithizone probably gives the most severe and rapidly developing lesion, while sodium fluoride gives the most localized reaction ophthalmoscopically and histologically. Ophthalmoscopic lesions are occasionally seen within a matter of a few hours, but more often not until about 48 hr.; fully established lesions are present almost always within 5 days.

These five agents do not seem to have very much in common chemically, nor apparently biologically; iodoacetate is a versatile enzyme inhibitor, dithizone produces experimental diabetes, and sodium fluoride is known mainly as an inhibitor of glycolysis. The mode of action of these five agents in producing retinotoxic damage is therefore obscure, and failure to obtain a protective effect from the use of possible protective substances—ascorbic acid[6] and vitamin E[7]—has not helped to clarify matters. In the rat, malic acid is protective against the lethal effect of iodoacetate, but enhances the retinal damage[8].

In the course of some work on possible protective substances, there was some suggestion that methionine might prove protective against the retinotoxic effect. The results were, however, not convincing, and as methionine is regarded as breaking up in the body into cystine and choline, and these two substances are antagonistic in experimental liver damage, it was thought best to study them separately. A preliminary trial with choline and cystine in the fasted rabbit suggested that cystine 50 mgm. intravenously 90 min. before and 90 min. after the administration of sodium iodate 17·5 mgm./kgm. intravenously was protective in 3 out of 4 animals treated. In contrast, choline in doses of 30 mgm. similarly administered was ineffective. Further work was continued with cysteine instead of cystine as it is more soluble and larger doses could be readily given intravenously. The procedure employed was to administer intravenously L (+) cysteine hydrochloride 300 mgm./kgm. (using 1 ml. of water per 100 mgm. of cysteine) on 5 days: twice on the day of the injection of the retinotoxic agent (90 min. before and 90 min after the injection) and once daily on the two previous days and the two subsequent days. The results obtained are shown in Table 1.

Table 1. EFFECT OF REPEATED DOSES OF CYSTEINE INTRAVENOUSLY IN RABBITS TREATED WITH FIVE DIFFERENT RETINOTOXIC AGENTS

Retinotoxic agent	Dose (mgm./kgm.)	No of animals treated	No died	Retinal lesions: Expected*	Present	Absent
Sodium iodate	25	10	0	10	0	10
Sodium iodoacetate	25	13	2	5–6	1†	10
" "	30	16	8	5	5†	3
" "	35	5	4	1	0	1
Dithizone	45	6	1	5	5	0
1 : 5 Di(p-amino-phenoxy)-pentane	5	10	1	9	9	0
Sodium fluoride	50	12	3	2	2	7

* In the case of sodium iodoacetate some 50 per cent are expected to show ophthalmoscopic lesions with doses of 25 mgm./kgm., 66 per cent with doses of 30 mgm./kgm., and almost all survivors with doses of 35 mgm./kgm. With sodium fluoride 50 mgm./kgm. some 20 per cent of survivors should show lesions With the other agents 100 per cent of treated animals should be affected with the dosage employed.

† These lesions were exceptionally mild both ophthalmoscopically and histologically compared to controls not treated with cysteine.

It will be seen that cysteine is fully protective against the retinotoxic effect of sodium iodate; the protective effect is only slightly less with sodium iodoacetate, judged by the fact that even with the larger doses of iodoacetate the ophthalmoscopic and histological reactions were very much milder in cysteine-treated animals than in controls. It would seem that cysteine has no protective effect against the remaining three retinotoxic agents listed.

These results suggest that the five retinotoxic agents known do not all exert their effect through the same mechanism, or that fuller doses of cysteine, and more effective methods of administration, might give control of the three agents uncontrolled in the present observation. Bearing on this latter possibility is the fact that protection appeared to be less effective when cysteine was given less intensively (either intravenously on the day of the injection of iodate only, or in the drinking water for several days).

Influence of 5-Hydroxytryptamine on Renal Function in Extracorporeal Circulation

A REDUCED renal blood flow and glomerular filtration-rate, despite a mean aortic pressure over the filtration-level, is a feature inherent to cardiopulmonary by-pass operations. Yet the maintenance of an adequate renal circulation is of primary importance in preventing ischaemic damage to the kidneys[1], and much research has been directed toward this special problem in the use of heart-lung machines. Accurate measurements on the critical flow-rate in various forms of by-pass were recently reported by Morris *et al.*[2].

Another harmful event in the use of current heart-lung machines is the destruction of thrombocytes. This seems to happen without regard to the type of oxygenator used[3] and can reach considerable dimensions. Recently my colleagues and I reported our observations on the humoral blood trauma in extracorporeal circulation[4]. The destruction of platelets was followed by a release of 5-hydroxytryptamine into the blood stream, resulting in elevated levels of this substance in the plasma and in its appearance in the urine. The changes in the urinary output, not earlier reported, had the same trend as during the use of heart-lung machines. Table 1 shows the actual values and the amount of 5-hydroxyindoleacetic acid, the main excretory product of 5-hydroxytryptamine, in the urine in periods before and during the extracorporeal circulation. The urinary output decreased in three dogs of four, from an average of 0·15 ml./min. before extracorporeal circulation to 0·07 ml./mm. during this circulation. In one dog the reverse was observed. Despite the elevated levels of 5-hydroxytryptamine in the plasma (on the average from 0·025 μgm./ml. to 0·045 μgm./ml.), the 5-hydroxyindoleacetic acid excretion measured per time unit showed a decreasing trend. This can scarcely be explained on any basis other than a renal factor. There is evidence that the renal excretion of 5-hydroxyindoleacetic acid parallels that of para-aminohippuric acid[5,6]. If this theory is correct, the 5-hydroxyindoleacetic acid excretion is dependent on both glomerular filtration and tubular excretion, and the changes in renal perfusion conditions in extracorporeal circulation explain as such the change under consideration. This concept is confirmed by the observation of a low urinary content of 5-hydroxyindoleacetic acid in the oligouric phase after open cardiac surgery[7] and it indicates that the urinary excretion of 5-hydroxyindoleacetic acid can give an unreliable impression of the decomposition of 5-hydroxytryptamine in conditions with a renal suppression. The possible role of renal pathology is discussed elsewhere[8].

Table 1. URINARY OUTPUT AND 5-HYDROXYINDOLEACETIC ACID (5-HIAA) EXCRETION IN EXTRACORPOREAL CIRCULATION

	Before extracorporeal circulation		During extracorporeal circulation	
	Urine flow	5-HIAA	Urine flow	5-HIAA
Dog 1	0 14 ml./min.	1·0 μgm./min. 7·1 μgm./ml.	0·09 ml /min.	0 4 μgm./mm. 4·0 μgm./ml.
Dog 2	0·22 ml./min.	0·7 μgm./min. 3·1 μgm./ml.	0·07 ml./min.	0·4 μgm./mm. 5·0 μgm./ml.
Dog 3	0 09 ml./min.	0·6 μgm./min. 6·5 μgm./ml.	0 04 ml./min.	0 4 μgm./min. 9 0 μgm./ml.
Dog 4	0 11 ml./mm.	0·8 μgm./min. 7 3 μgm./ml.	0·28 ml./min.	0·3 μgm./mm. 0 9 μgm./ml.

Considering together the reduced urinary flow and the release of 5-hydroxytryptamine from disintegrated platelets, it seems reasonable that these two phenomena are to some degree interrelated, especially in view of the antidiuretic properties of 5-hydroxytryptamine. There is no general agreement with the original concept of Erspamer[9] that the physiological role of 5-hydroxytryptamine is that of a renal hormone. There are, however, several studies, well controlled to avoid the interference of hypotension, that show a clear-cut antidiuretic effect of exogenous 5-hydroxytryptamine[10,11]. According to these studies, infusions of 5-hydroxytryptamine at dose-levels of 5–15 μgm./kgm./min. had a definite antidiuretic effect in dogs and rats. Also, 5-hydroxytryptamine infused into normal people reduced the renal blood flow and glomerular filtration-rate[12]. The same antidiuretic effect certainly applies to endogenously released 5-hydroxytryptamine. Of special interest in this connexion are the findings of Watkins[13]. He observed that the renal suppression began already within 5 min. after the start of a dog by-pass at an adequate perfusion and arterial pressure and with minimal acid-base change. This type of a rapid renal suppression is rather to be related with some humoral agent in the circulating blood than with perfusion and pressure conditions.

Several factors in the use of heart-lung machines, many of them common in major surgery in general, can affect the renal function, perfusion rates clearly playing a central part. The release of 5-hydroxytryptamine, a substance with antidiuretic properties, in extracorporeal circuits, with a simultaneously reduced urinary output, suggests that this substance may also play a part in the renal hæmodynamics of by-pass operations and major surgery in general. Also the liberation of adenosine triphosphate[4] has to be taken into account since this substance releases antidiuretic hormone from the posterior pituitary[14]. Clinical studies are in progress to clarify further the problem under consideration.

The 5-hydroxyindoleacetic acid was generously supplied by Upjohn Co., Kalamazoo, Mich.

PATHOLOGY

Anti-Inflammatory Activity of Salicylate

Salicylate uncouples oxidative phosphorylation reactions[1], and the possible relation of this major action on cellular metabolism to other effects of the drugs is of great interest[2]. One of the most important properties of salicylate is its anti-inflammatory actions, both in rheumatic disease and in experimental inflammatory states[3]. Adams and Cobb[4] observed a general parallelism between uncoupling activity and the inhibition of erythema in the guinea pig by a series of non-hormonal anti-rheumatic drugs, including salicylate. They suggested a possible connexion between uncoupling ability and therapeutic activity but found that 2 : 4-dinitrophenol, which is a more powerful uncoupling agent than salicylate, failed to affect the erythema test. We have observed that salicylate, but not 2 : 4-dinitrophenol, also modifies the response to the passive cutaneous anaphylaxis test in the guinea pig.

In this test, the animals, after depilation, were given an intradermal injection of antibodies to pneumococcal type III polysaccharide, followed 24 hr. later by the intravenous injection of the antigen and pontamine blue. A progressive formation of œdema and leakage of the circulating dye then occurs in the areas of skin in which the antibodies have been injected. Animals given an intraperitoneal injection of salicylate (500 mgm./kgm. body-weight), 2 hr. before the injection of the antigen and dye, showed a reduced leakage of the circulating dye, but the area in which the extravasation of dye occurred was not changed. Similar treatment with 2 : 4-dinitrophenol (20 mgm./kgm. body-weight) had no effect compared to corresponding control animals.

These observations suggest that the anti-inflammatory action of salicylate, as exerted in the erythema and passive cutaneous anaphylaxis tests, does not result from an uncoupling action on oxidative phosphorylation processes and must be produced by another mechanism.

Full details of the experiments described above will be published elsewhere.

Fate of Homologous Adult Spleen Cells Injected into New-born Mice

During a series of experiments involving radiation chimæras, it became increasingly evident that it would be necessary to consider the results in terms of immunological tolerance of the actively acquired type. At the time a cytological marker was being used for tracing donor cells in the radiation chimæras, following the technique of Ford, Hamerton, Barnes and Loutit[1]. It was decided to use the same marker in tracing cells injected into new-born animals in order to determine, by a direct method, to what extent chimærism is a necessary adjunct to tolerance. There is considerable circumstantial evidence that this is indeed the case[2,3].

5×10^6 spleen cells of the *T6/T6* strain were injected intravenously into either C^- or *CBA* litters within 24 hr. of birth. In three cases C^- cells were injected into *T6* babies. At various time-intervals after injection, animals were killed and the spleens were prepared for cytological analysis by a modification of the technique of Ford and Hamerton[4]. Table 1 records the results of preliminary experiments. Injection of homologous adult spleen cells into the new-born animals resulted in splenomegaly and runting, a well-known phenomenon[2,5,6].

The rates of division in all spleens investigated, except that of the six-months-old animal, were abnormally high and there were other signs of an

Table 1. A Cytological Analysis of the Spleens of Animals Injected at Birth with Adult Spleen Cells, Chromosomally Marked

immunological activity which is thought to be basically a graft-versus-host attack. The only thing lacking in the spleens analysed (Table 1) was the high proportion of dividing donor type cells which has been postulated[3]. Contrary to expectation, splenomegaly in young mice injected at birth with homologous adult spleen cells does not appear to be due primarily to proliferation of the donor cells. Recently, Isacson[7] came to the same conclusion on rather less-direct evidence. Biggs and Payne[8] reported that enlarged spleens in nineteen-day-old chick embryos injected with homologous spleen cells at 14 days of incubation contained roughly equal proportions of donor and host cells.

A more comprehensive series of experiments will be published when the results have been fully analysed.

Proliferative Capacity of Acute Leukæmia Cells

SEVERAL investigations have been carried out with the purpose of detecting some peculiarities in the deoxyribonucleic acid of leukæmic cells, particularly its content, its base composition and several of its physico-chemical characteristics. It can be expected that more valuable information might be obtained from the study of deoxyribonucleic acid metabolism than from the simple analysis of its static properties. The incorporation of several precursors of deoxyribonucleic acid in the total leucocyte pool has been investigated with chemical methods[1–3]. An increased uptake has been detected in leukæmic marrows as compared with normal ones[1,2]. However, such a study does not allow a direct comparison between normal and pathological marrows since with these techniques the importance of different leucocyte populations of various degree of maturation is necessarily overlooked. That holds particularly for acute leukæmia cells, of which the normal counterparts (that is, normal myeloblasts) represent only about 4 per cent of the whole cellular population in a normal bone marrow.

Radioautography is considered at present as the best technique for an investigation at a cellular level. With this technique Lajtha[4] has studied the incorporation of phosphorus-32 and of adenine-^{14}C into the deoxyribonucleic acid of human bone marrow cells *in vitro* and obtained valuable results concerning the kinetics of cellular division.

In the past few years the availability of thymidine labelled with tritium has allowed the use of the most specific precursor of deoxyribonucleic acid (thymidine) and, at the same time, it has enormously increased the resolution of the technique (tritium labelling)[5–8].

The present investigation deals with the incorporation of tritium-labelled thymidine, as studied with a radioautographic technique in bone marrow cells of five normal individuals and of 13 patients with acute leukæmia.

Bone marrow was obtained by sternal puncture and aspiration into a heparinized syringe, diluted 1/1 with Eagle medium and transferred into siliconized test tubes. ^{3}H-thymidine (specific activity 890 mc./m*M*) was added to a final concentration of 2·5 μc./ml. Incubation was carried out in a rotating system at 37°. After 1, 3 and 5 hr. smears were made on gelatine-coated slides. The smears were fixed in Carnoy's solution and, after several washings in distilled water, radioautographic preparations were obtained according to the current technique[9]. The percentage of labelled cells was determined, in each case, counting at least 100 myeloblasts for the normal and 2,000 blast cells for the leukæmic marrows.

The strikingly lower incorporation of thymidine labelled with tritium in acute leukæmia cells as compared to that detected in normal myeloblasts is shown in Table 1. No significant variations in the percentage of labelled cells were observed among the different normal bone marrows. In all cases, between the first and the fifth hour of incubation, the percentage of labelling did not significantly increase.

Table 1. PERCENTAGE OF LABELLED MYELOBLASTS AFTER 1 HR. INCUBATION

Normal bone marrows	Acute leukæmias			
	Stem cells	Myeloblastic	Monoblastic	Lymphoblastic
50	1·0	0·2	5·4	1·5
45	1·4	9·4		
35	3·3	4·0		
40	2·7	7·0		
35	9·1			
	2·8			
	1·0			
Mean value 41 ± 6·5	3·0 ± 2·3	5·1 ± 4		

It is well known that the incorporation of thymidine, as evidence of synthesis of deoxyribonucleic acid, occurs only as a preparation for later mitosis. It is therefore considered to be the most reliable index of the proliferative capacity of a tissue. The low percentage of labelling detected in acute leukæmia cells therefore indicates an extremely low proliferative capacity of these elements. Our results are in good agreement with those previously suggested by other investigators utilizing bone marrow cultures and the stathmokinetic test[10,11].

These results are in contrast with the current opinion of a high mitotic activity of leukæmic tissues, and suggest that in acute leukæmia elements, as compared to their normal counterparts, another important functional defect is present associated with the well-known incapacity to differentiate. This consideration might be of some importance in regard to a more rational therapeutic approach in acute leukæmia.

We wish to thank Prof. G. C. Dogliotti for his helpful suggestions.

RADIOBIOLOGY

Removal of Internally Deposited Americium by Chelating Agents

DURING recent years there has been considerable interest in the use of chelating agents to remove certain radioelements deposited in the body. Ethylenediamine tetraacetic acid has been investigated extensively, and more recently there have been reports that diethylenetriamine pentaacetic acid is more effective than ethylenediamine tetraacetic acid for the removal of deposited plutonium[1], and that it also increases the excretion of thorium from the body[2]. We have studied the effect of these two chelating agents on the removal of americium-241 from the rat. Preliminary experiments showed that both reagents significantly increased the excretion of this nuclide and that diethylenetriamine pentaacetic acid was approximately twice as effective as ethylenediamine tetraacetic acid.

Groups of three young male hybrid rats of the F_1 generation bred from Marshall and August parents were injected intravenously with 0·2 μc. americium-241 as the citrate complex. Treatment with 0·3 m.mole diethylenetriamine pentaacetic acid and 0·2 m.mole calcium gluconate, given by intraperitoneal injection in 2 ml. of solution, was started at times varying from 1 hr. to 7 days after the injection of americium-241 and repeated at weekly intervals. The rats were killed 21 days after the injection of americium-241 and the alpha activities of the liver, femur, carcass and excreta were measured by the technique described by Turner, Radley and Mayneord[3].

In Fig. 1 the distribution of americium-241 twenty-one days after administration to a normal animal is compared with that in animals treated with diethylenetriamine pentaacetic acid at various intervals. The untreated animals contain approximately 40 per cent of the injected activity in the skeleton, 25 per cent in the soft tissues, and excrete about 35 per cent. When treatments with diethylenetriamine pentaacetic acid were commenced at 1 hr., 6 hr. and 7 days after the administration of americium-241, the levels in the skeleton were 7, 10 and 20 per cent, respectively, and the amounts in the soft tissues were reduced to less than 1 per cent of the injected activity. Most of the americium-241 that was removed was excreted in the urine.

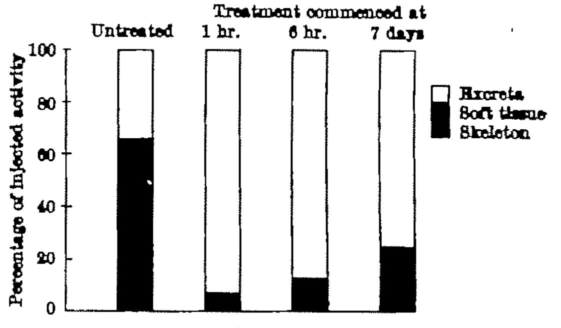

Fig. 1. Effect of diethylenetriamine pentaacetic acid on the distribution and excretion of americium in rats

It is concluded that diethylenetriamine pentaacetic acid can remove americium-241 from the skeleton and soft tissues, and that an appreciable reduction in the body burden can be achieved, particularly when the agent is administered within a few hours after exposure.

This work will be more fully reported in a later publication, which will include a comparison of the effects of multiple and single doses of chelating agent, and the effects of oral and intraperitoneal administration.

We wish to thank Prof. W. V. Mayneord and Dr. L. F. Lamerton for their help and encouragement, and the Geigy Company, Ltd., which generously supplied the diethylenetriamine pentaacetic acid.

Radiosensitivity of Mouse Kidney undergoing Compensatory Hypertrophy

WE have been interested in assessing the degree or extent of acute radiation damage to the kidneys, particularly as it may relate to late radiation effects on this organ, namely nephrosclerosis[1,2]. Significant acute changes in renal morphology (that is, during the first month), following whole-body irradiation in the lethal dose-range, have not in general been observed[3,4]. In this connexion, it is well known that the kidney of the normal adult exhibits only minimal mitotic activity. Therefore it was thought of interest to ascertain whether the kidney becomes radiosensitive when mitotic activity is stimulated by unilateral nephrectomy. Mitotic activity of the kidney following unilateral nephrectomy has been shown by Rollason[5] and by Sulkin[6] to be largely restricted to the period 48–72 hr. post-surgery.

Female mice of the $(C57L \times A)F_1$ hybrid strain were employed. A total of eighty 10-week-old animals were subjected to left unilateral nephrectomy under ethyl ether anaesthesia. The left adrenal gland was dissected free from the kidney with its blood supply intact, and spared. The excised kidney was gently blotted and weighed in a glass-stoppered weighing bottle to the nearest milligram. In a series of normal mice, comparison of the left and right kidney weights in each animal showed no more than 5 per cent difference—the right kidney being the larger in every case. These mice were divided into four sub-groups, approximately 15 each. One sub-group was X-irradiated in a single whole-body exposure to 690 r. (a high sublethal dose) 3 hr. after surgery. Another sub-group constituted a non-irradiated control group. A third sub-group of nephrectomized mice was X-irradiated similarly (690 r.) 48 hr. after surgery, with the fourth sub-group serving as the non-irradiated controls. A fifth sub-group was irradiated (690 r.) 1 hr. prior to unilateral nephrectomy. Of the 80 original mice, 75 were killed three weeks after surgery (a time at which compensatory hypertrophy of rat kidney has been shown to reach a plateau[6]), and the remaining right kidney removed and weighed. Kidneys from four of the original mice were removed 48 hr. after nephrectomy, and fixed in formalin for histological examination. One mouse of the 80 died 7 days post-irradiation. For determination of mitotic activity, kidney sections were stained with Feulgen reagent, and mitoses per 50 high-power fields were calculated. The X-radiation source was a Westinghouse therapy unit, operated at 250 kVp. The radiation factors were: 15 m.amp.; filter 0·5 mm. copper plus 1 mm. aluminium; half-value layer 1·5 mm. copper; target-skin distance 100 cm.; dose-rate 30 r. per min., in air.

A summary of the results showing the percentage increase in kidney weight in each animal, relative to the initial left kidney weight, is presented in Fig. 1. It is evident that in the group irradiated (690 r.) 48 hr. post-nephrectomy, compensatory hypertrophy of the right kidney was not inhibited, as compared with that of non-irradiated, nephrectomized controls. Many of the kidneys in both these groups showed increases in weight up to 50 per cent. By contrast, unilaterally nephrectomized mice exposed to 690 r. 3 hr. post-surgery showed only a minimal increase in weight of kidney—only one kidney showing increase in weight of as much as 21 per cent, the bulk of the remainder showing weight increases of 10 per cent or less.

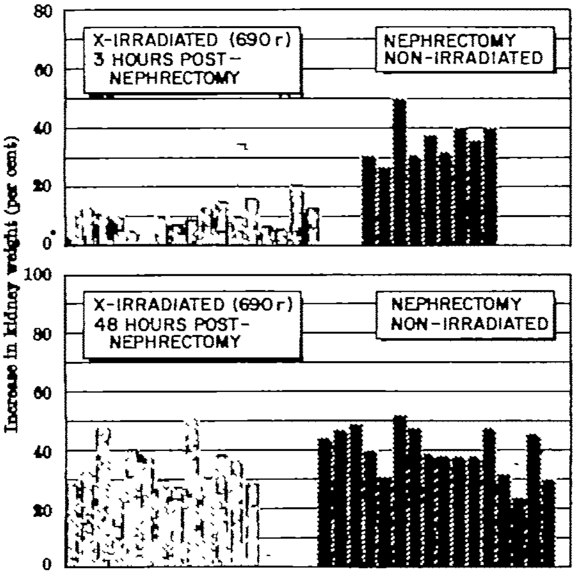

Fig. 1. Inhibition of compensatory hypertrophy of mouse kidney by X-irradiation (690 r.) 3 hr. post-nephrectomy

The weights of the normal left kidneys ranged from 86 mgm. to 159 mgm., with a mean of 121 mgm. The corresponding weights of the right kidneys extirpated from the non-irradiated mice 3 weeks post-surgery ranged from 127 mgm. to 203 mgm., with a mean of 167 mgm. By contrast, weights of the right kidney of mice irradiated 3 hr. post-surgery ranged from 114 mgm. to 170 mgm. (mean of 137 mgm.), as compared to weights of the right kidney of mice irradiated 48 hr. post-surgery with a range of 120–205 mgm. (a mean of 167 mgm.).

Mitotic counts were determined on the right kidneys removed from two non-irradiated control mice 48 hr. after left unilateral nephrectomy, and also on corresponding kidneys from two 690 r. irradiated mice (3 hr. post-nephrectomy), killed 48 hr. after surgery. In the non-irradiated mice, 136 and 147 mitoses, respectively, per 50 high-power fields were observed. By comparison, the kidneys of the irradiated mice (irradiated 3 hr. post-nephrectomy) showed only 7 and 5 mitoses per 50 high-power fields 48 hr. after surgery. (One high-power field contains approximately 400 cells.) The mitotic figures were distributed proportionately between cortex and medulla. Corresponding values for normal, non-irradiated kidneys were 5 and 8 mitoses per 50 high-power fields, respectively.

When 690 r. X-radiation was delivered 1 hr. prior to nephrectomy, no inhibition of capacity of the kidney to undergo compensatory hypertrophy could be detected. The weights of the left kidney from this group (that is, at the time of unilateral nephrectomy) ranged from 98 mgm. to 140 mgm., with a mean of 118 mgm. The weights of the right kidney, that is, three weeks post-nephrectomy, ranged from 129 mgm. to 205 mgm., with a mean of 168 mgm. The percentage weight increase of right kidney over left kidney varied from 30 to 54 per cent, with a mean increase of 42 per cent.

The foregoing results indicate that the mouse kidney is radiosensitive during a critical time period following a stimulus to cell division, namely unilateral nephrectomy. If the irradiation (690 r.) is carried out 2–3 hr. post-nephrectomy, there is a marked inhibition both of mitotic activity at 48 hr., and of compensatory hypertrophy, as measured at 3 weeks post-surgery. By contrast, when irradiation (690 r.) is carried out 48 hr. post-surgery, the capacity of the kidney to undergo compensatory hypertrophy is not impaired. It seems evident that the radiosensitivity of the kidney 3 hr. post-unilateral nephrectomy is somehow related to its cellular activity following upon the stimulus which leads to cell division—presumably preparation for deoxyribonucleic acid synthesis, since Becker and Ogawa[7] have demonstrated an increase in the amount of deoxyribonucleic acid per nucleus under these conditions of mitotic activity in the kidney. Recent studies by Beltz and Applegate[8] on regenerating liver would appear to shed further light on this problem, at the biochemical level. These workers subjected rats to partial hepatectomy, exposed them to 1,500 r. at 12–13½ hr. post-surgery, and killed them 25 hr. after surgery; assay for incorporation of thymidine labelled with tritium into deoxyribonucleic acid by the liver supernatant fractions *in vitro* was then carried out[8]. It was found that the liver supernatants from the irradiated partially hepatectomized rats possessed only 10 per cent of the capacity of the same tissue fractions from non-irradiated controls to incorporate labelled thymidine into deoxyribonucleic acid. They conclude that the effect of irradiation "is to prevent the synthesis, or the production of zymogen activation of one or more enzymes in the group of enzymes functioning to incorporate thymidine into deoxyribonucleic acid". It is tempting to speculate on the radiation-inhibition of compensatory hypertrophy in the kidney, presented in this report, in terms of similar mechanisms.

This investigation has been supported in part by funds from the Bureau of Medicine and Surgery, U.S. Navy Department, and from the Office of Civil and Defense Mobilization. The opinions and assertions contained herein are not to be construed as official or as reflecting the views of the Navy Department.

Uptake of Thymidine and Synthesis of Deoxyribonucleic Acid in Mouse Ascites Cells

Recent studies of the synthesis of deoxyribonucleic acid have suggested that the radiation-sensitive period may occur at a stage in the cell-cycle before the polymerization of new deoxyribonucleic acid begins, that is, during the G1 period[1–3]. It therefore appeared to be of interest to study, in more detail, the assimilation of the precursors into cells and their subsequent incorporation into deoxyribonucleic acid. With this object we have examined the uptake of thymidine labelled with tritium into mouse Ehrlich and Landschutz ascites cells *in vitro*, measuring the total activity present in the cell and the activity incorporated into deoxyribonucleic acid, as a function of time. The distribution of the precursor among the cells of the population was determined by autoradiography. 2 ml. aliquots of suspension containing about 10^8 cells were incubated at 37° in a medium containing 50 per cent ascitic fluid and 50 per cent fortified Hanks' medium[4] (5 gm. glucose/l.). At the end of the incubation the cells were washed five times with ice-cold Hanks' medium and finally suspended in 4 ml. of the medium. Autoradiographs were prepared in the usual manner, the cells being air dried, fixed with 2 per cent acetic acid or with 45 per cent acetic acid in alcohol and washed before the application of the stripping film. Deoxyribonucleic acid was prepared from 2 ml. of the cell suspension using the detergent method of Kay, Simmons and Dounce[5], the final product being dissolved in 2 ml. of water. The solutions of deoxyribonucleic acid and the cell suspensions were homogenized by treatment with ultrasonics before plating on aluminium planchettes. Determinations of tritium activity were made using a windowless flow counter working in the proportional region with an efficiency of about 15 per cent. Deoxyribonucleic acid contents of the cell suspensions and acid solutions were determined using the modified diphenylamine method of Burton[6].

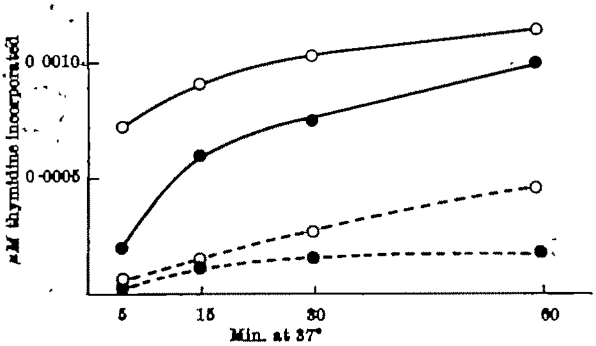

Fig. 1. Incorporation of tritium-labelled thymidine into cells and deoxyribonucleic acid. *a*, 0·001 μM, 2 μc. ^{3}H-thymidine, ●—● cells, ●- - -● deoxyribonucleic acid; *b*, 0·01 μM, 5 μc. ^{3}H-thymidine, ○—○ cells, ○- - -○ deoxyribonucleic acid

The general pattern of the results obtained for both types of cells is illustrated in Fig. 1. Thymidine is rapidly taken up by the cells, but the rate of incorporation into deoxyribonucleic acid is much slower. The amount of thymidine which the cells can take up is limited. For example, when 0·001 μM of thymidine is added to a suspension containing about 10^8 cells, nearly all of it is taken up by the cells in 1 hr., but when ten times this amount of thymidine is added the amount taken up in 1 hr. is only slightly increased. The amounts of tritium-labelled thymidine in the cells and in the deoxyribonucleic acid are not increased appreciably by longer periods of incubation (up to 3 hr.). Addition of the other three nucleosides does not influence the amounts taken up. The failure of the cells after 1 hr. to take up more thymidine or to synthesize more deoxyribonucleic acid is not due to a general stopping of the metabolic processes of the cells since the rate of incorporation of orotic acid into the ribonucleic acid continued at a constant rate for at least 2½ hr. Neither can the effect be attributed to damage caused by radiation from the labelled thymidine present in the cells, since the amount of precursor taken into the cells and incorporated into the deoxyribonucleic acid is the same if 0·01 μM of thymidine is added with an activity of 5 μc. or 0·5 μc. It appears that when the cells are incubated in this medium some changes occur or some metabolite is lacking which prevents them from either accumulating thymidine or synthesizing deoxyribonucleic acid for more than a short time.

We have also attempted to ascertain the nature and distribution of the precursor which is present in the cells but not polymerized into deoxyribonucleic acid. Nuclei were prepared using the method of Allfrey *et al.*[7], and the non-nuclear fraction was found to contain scarcely any activity. The autoradiographs also showed that the precursor was concentrated in the nuclei of the cells. Very little activity was lost from the nuclei on standing in Hanks' medium and no exchange was detected when inactive thymidine was added to the medium. It was, however, found that treatment of the cells or nuclei with ultrasonics and centrifuging for 20 min.

at 100,000g left considerable amounts of activity in the supernatant fraction. Chromatography of these supernatant fractions (*iso*butyric acid/ammonia solvent) obtained from cells incubated for 1, 5 and 16 min. showed that the activity of tritium was accounted for as 15 per cent thymidine di- and tri-phosphates (these two compounds were assayed together), 25 per cent thymidine monophosphate and 60 per cent thymidine in all cases. These results suggest that thymidine is taken up by the cells and transferred to the nucleus where an equilibrium is rapidly set up between thymidine, thymidylic acid and the di- and tri-phosphate derivatives. Although these compounds cannot be simply washed out from the cells or nuclei, it appears that they are not firmly bound within the nucleus since they can be liberated by destroying the nuclear structure. It seems probable that some part of the precursors may be even more firmly bound within the nucleus since the activity of the supernatant fractions obtained after ultrasonic treatment, added to the observed activity of the deoxyribonucleic acid, accounts, in some cases, for only 60 per cent of the total activity of the cells.

Table 1. COMPARISON OF THE TRITIUM ACTIVITY OF CELLS AND DEOXYRIBONUCLEIC ACID AND THE DEGREE OF LABELLING OBSERVED IN AUTORADIOGRAPHY EXPERIMENTS

Minutes incubated at 37° C.	C.p.m./μgm. deoxyribonucleic acid in the cell suspension	C.p.m./μgm. deoxyribonucleic acid in the isolated deoxyribonucleic acid	Average spots per cell in autoradiograph	Fraction of cells labelled in autoradiograph (per cent)
15	115	32	7·1	32
60	119	79	5·5	29

It has usually been considered that the activity observed, in the nucleus, by autoradiographic procedures after appropriate washing and fixing techniques can be ascribed to the thymidine incorporated into deoxyribonucleic acid[8]. The results of this work show that this is not necessarily valid. It can be seen, for example, in Table 1, that after 60 min. incubation the average amount of tritium-labelled thymidine assimilated per cell is little different from that observed after 15 min. incubation, though more than twice as much of the thymidine has been incorporated into deoxyribonucleic acid. The data from the autoradiographs suggest that the average activity per cell is roughly the same for the two periods of incubation and clearly bears no relationship to the activity of the deoxyribonucleic acid alone. It would therefore appear that the fixing procedure does not remove a significant part of the labelled thymidine, which is incorporated into the cell but not polymerized into deoxyribonucleic acid. To confirm this conclusion a suspension of washed cells was centrifuged and the cells resuspended in (*a*) 2 per cent acetic acid and (*b*) 45 per cent acetic acid in alcohol. After standing for 5 min. at room temperature the suspensions were centrifuged and the activity of the supernatant fractions assessed. In both cases the total activity of the fixing fluids was less than 10 per cent of the total activity of the cell suspension. Table 1 also shows that only one-third of the cells in the suspension have assimilated labelled thymidine. It would therefore appear that under the conditions used in our experiments, the autoradiographic process detects not only the cells which are actively polymerizing new deoxyribonucleic acid but also those which contain precursors in a form not easily removed by the washing and fixing procedures (cf. Harris)[9]. Other workers have attempted to assess mitotic activity from counts of the number of labelled cells in autoradiographs and have found an apparent index considerably greater than that obtained from experiments using colchicine to inhibit cell division[10]. The results described above could provide an explanation for this anomaly.

We are indebted to Prof. J. A. V. Butler for encouragement in this work. We also wish to thank B. Hunter and B. Wilson for technical assistance. Effects of Whole-body Irradiation on the Breeding Plumage of the Weaver finch, *Quelea quelea*

THERE have been recent unsubstantiated reports that individuals of certain migratory species of birds have arrived in their African wintering grounds in breeding plumage instead of their normal eclipse condition[1]. Again, several migratory waders have been collected in Great Britain in unseasonal plumage. Some have been found to be radioactive; an examination has shown in some of the birds stimulation effects of the neuro-endocrine apparatus abnormal for the season (Harrison, J. M., personal communication). There is no evidence that the two factors are related, but the possibility that the anterior pituitary and sexual cycle, involving plumage changes, have been artificially disturbed by radiation could not be overlooked.

In order to investigate whether such phenomena can be produced by radiation, seasonally dimorphic weaver finches (*Quelea quelea*) were imported from Africa. In this species the male periodically assumes a vivid nuptial plumage, and after reproduction moults into non-breeding plumage which is indistinguishable from that of the permanently sombre female[2]. This cyclical assumption of a brilliant nuptial plumage is, as in certain other African weaver finches, under the direct influence of the adenohypophysis[3] and has been adopted by Witschi as a bio-assay test for gonadotrophins. He and his co-workers showed that

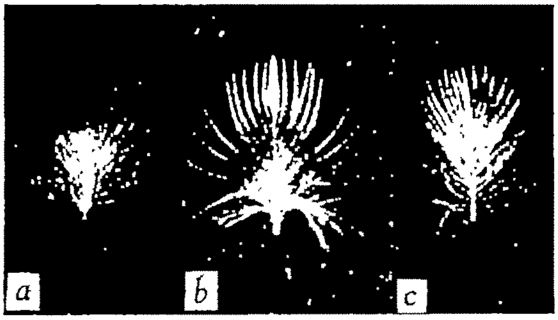

Fig 1. (a) Male feather regenerated after 1,000 r. Tip normal and pigmented but post-irradiation growth is unpigmented. (b) Female feather showing band of abnormal melanin deposition after whole-body irradiation of 200 r. (c) Unpigmented control female feather

the deposition of melanin in regenerating feathers is a specific reaction to luteinizing hormone[4].

In a preliminary experiment six groups each of 12 individuals (6 males and 6 females) were used. All these were in full breeding condition, all the males displayed the complete nuptial plumage of black facial mask and golden crown and breast, and all the females bright yellow beaks and drab plumage. Feathers were plucked from the black face-mask area of all birds, which were then left for four days, during which new feathers began to grow. Five of the six groups were then subjected to a single whole-body exposure of 15-MeV. X-rays at doses of 50 r., 200 r., 400 r., 800 r. and 1,000 r., respectively. The sixth was retained as a control group. The source of radiation was the 15-MeV. linear accelerator at St. Bartholomew's Hospital[5], and the dose-rate was about 500 r./min.

The feathers that regenerated in the plucked facial mask of male controls were identical with those removed before irradiation. In both cases they were black. In all the irradiated birds except those that received a dose of 1,000 r., the regenerated cock feathers were of the black type and indistinguishable from those of the controls. The regenerated plumage of the three survivors of the 1,000 r. exposure (approximately the *LD*50 for this species with this type of radiation), however, was unpigmented except at the feather-tips, which had been laid down in the four days before irradiation. No melanin was deposited in the parts of the feathers that had grown after irradiation (Fig. 1*a*).

Females of this species do not cyclically assume coloured breeding plumage, and so feathers removed from the facial mask area before irradiation were white and unpigmented. Regenerated feathers in female controls were unchanged, but those in the 50 r., 200 r. and 400 r. groups now displayed a black band of melanin deposition. The tips, which had developed before irradiation, were light and of normal hen colour. After irradiation, however, this normally coloured tip was succeeded by a band of melanin deposition of a kind that normally occurs only in cocks. The feather base was again hen-type and white (Figs. 1*b* and 1*c*). It is important to mention, however, that in the two higher-dosage groups melanin deposition did not occur and the regenerated plumage remained of the normal hen type.

All birds underwent a normal post-nuptial moult into the eclipse condition in July. By September, male birds were once again starting to assume their nuptial plumage.

A second experiment was performed on *Quelea* while the birds were in eclipse condition. Three groups of 24 such specimens were deplumed in the mask area and their feather follicles allowed to reorganize. One group was then given a dose of 100 r. of whole-body irradiation, another 800 r., and the third group was retained as a non-irradiated control. They were then left until the feathers had regenerated, when it was found that in all cases the new feathers were apparently normal, unpigmented and typical of the eclipse condition.

The abnormal deposition of melanin in the plumage displayed by female birds may be indicative of pituitary stimulation induced by the lower irradiations. This, however, appears to be only a temporary condition, for the birds soon reverted to their natural plumage and underwent normal moult cycles. Whether an exposure at a much lower dose-rate would have a prolonged stimulatory effect, and afterwards extend the period of melanin deposition, is not known and is under investigation.

We wish to thank the Nuffield Foundation for its support of this and allied studies.

BIOLOGY

Breeding Sites of Non-Cichlid Fishes in Lake Victoria

Breeding sites in Lake Victoria are known for three of the non-cichlid fishes. The lung-fish, *Protopterus aethiopicus* Heckel, constructs a nest in marginal swamp[1], and the cat-fish, *Clarias mossambicus* Peters[2], and the carp, *Labeo victorianus* Blgr.[3], spawn in temporary streams which flow into the lake after rain.

A study of the food of non-cichlid fishes in the Lake Victoria basin has recently been completed, and some of the findings, when considered in conjunction with other ecological facts, have indicated that in the lake two species, *Bagrus docmac* (Forskal) and *Mormyrus kannume* (Forskal), may breed on exposed rocky shores. The evidence is stated below.

The geological history of Lake Victoria[4] indicates that it has been colonized relatively recently by fishes of swamps and rivers[5]. Several non-cichlid fishes now inhabiting the lake periodically ascend affluent rivers *en masse*, presumably to breed[6]. *Bagrus* and *Mormyrus*, however, do not do this;

Table 1. NON-CICHLID FISHES COLLECTED FROM A ROCKY SHORE IN LAKE VICTORIA

Species	No. collected	Size-range (cm.)	Median (to nearest cm.)
Bagrus docmac (Forskål)	41	3–16	8
Clariallabes petricola Greenwood	34	3–11	6
Mastacembelus victoriae Boulenger	31	3–27	10
Clarias mossambicus Peters	15	3–14	11
Mormyrus kannume (Forskål)	8	11–20	14
Clarias werneri Boulenger	3	7–10	10
Engraulicypris argenteus (Pellegrin)	1	5	—
Synodontis afro-fischeri Hilgendorf	1	11	—

Bagrus takes part in the upstream migrations, but only in relatively small numbers[6], and therefore, like *Mormyrus*, must be assumed to breed within the lake itself. Juveniles of both these species had hitherto only been found in numbers in torrential reaches of the effluent Victoria Nile at Jinja, where they fed on lithophilic insects among the stones of the river bed. In the lake the habitat most resembling this environment is the exposed rocky shore, where many of the same insects (for example, *Afronurus*, *Neoperla*, *Metaonemis* and *Phanostoma*) typically occur. In the Victoria Nile juveniles of both fishes feed on lithophilic insects, but the adults on foods derived elsewhere. In the lake, individuals of these species below 15 cm. are scarcely ever found, but the food of fishes larger than this (of which more than 4,000 have been examined) changes according to their size, so that they feed progressively less on lithophilic organisms as they become older. Thus, although samples of fishes from the lake included no juveniles, they revealed ontogenetic changes in feeding behaviour which paralleled those observed in the river. This may therefore be regarded as additional evidence for supposing that in the lake exposed rocky shores provide the habitat for juveniles.

To test this supposition a small fish-poisoning operation was carried out on February 13 at Entebbe, along a short strip (about 50 m. × 3 m.) of rocky shoreline, exposed to unusually vigorous wave-action. The results (Table 1) confirm expectation in two important respects: they make it virtually certain that in the lake such a habitat provides a breeding site for *Bagrus*; and they emphasize the ecological similarity which exists between rocky shores in the lake and turbulent reaches in associated rivers. Whether or not *Mormyrus* also breeds on such shores must at present remain an open question, although the evidence given earlier indicates that this may be so. It should be noted that one Entebbe specimen of 20 cm. total length was a ripe female.

The presence of numerous *Clariallabes petricola* Greenwood is particularly informative, since not only is this the first record of this species from the lake proper but its type habitat[7] is the very spot where juvenile *Bagrus* and *Mormyrus* were found in the Victoria Nile. One female (6 cm. total length) from Entebbe had ripe gonads. Here it should be mentioned that another fish to be newly recorded from Lake Victoria, and also collected previously from the Victoria Nile site[7], is *Garra johnstoni* (Blgr.), which was found recently on an exposed loose-rock shore at Entebbe by Mr. J. P. C. Greenway.

Another significant feature of the results is the abundance of *Mastacembelus victoriae* Blgr., which was actually the commonest fish on the site. Like *C. petricola*, this species had previously been found to be very common on the bed of the Victoria Nile[2], but had hitherto been encountered only rarely in the lake, presumably because the appropriate habitat there had not been sampled. Thus, these observations correspond well with the report that in Lake Nyasa *Mastacembelus shiranus* Günther was encountered commonly only when fish-poisoning was carried out on rocky shores[9]. At Entebbe three *M. victoriae* (10, 16 and 26 cm. total length) were ripe females.

Although the specimens of *C. mossambicus* are too large to indicate that breeding was occurring in this site, it is perhaps significant that fishes of this estimated age (6–12 months) should be found in such an environment where, as in the temporary streams in which they are spawned[8], there is vigorous water movement.

From the observations recorded here it may be concluded that the fauna of wave-washed rocky shores in Lake Victoria closely resembles that of turbulent reaches in associated rivers (from which it presumably originated), and that consequently the rocky shore may be considered to constitute an important transition habitat able to accommodate the least-adaptable stages in the life-histories of those riverine fishes in process of becoming lacustrine. It follows that systematic studies of rocky shores may be expected to produce much valuable information concerning the ecology and evolution of non-cichlid fishes in the lake.

B. docmac is one of the non-cichlids caught most frequently by fishermen in Lake Victoria. That it should breed on rocky shores promises well for its future utilization, for it is likely that in the normal course of events neither man nor natural predators will interfere significantly with such a habitat.

I am grateful to Messrs. D. H. Rhodes and J. P. C. Greenway for assisting with the fish-poisoning operation, and to Mr. P. H. Greenwood for identifying and estimating the age of the Clariidae.

A full account of the work leading to these conclusions will be published elsewhere.

Occurrence of Free D-Serine in the Earthworm

LOMBRICINE was first isolated from the earthworm by Thoai and Robin[1]. Analysis of the crystalline material isolated in this laboratory[2] showed that the serine component was of the D-configuration[3]. Serine ethanolamine phosphodiester, which has been shown to be a precursor of lombricine in the earthworm[4], has been isolated in the crystalline form and shown to contain D-serine[5].

We now wish to report the finding of free D-serine in the acid-extractable free amino-acid pool of the earthworm.

The earthworms used were deep-frozen material of mixed species, but predominantly *Allobophora caliginosa* and *Octolasium cyaneum*. Extracts were prepared and fractionated as described[5] for the isolation of lombricine and serine ethanolamine phosphodiester; those fractions containing serine were identified chromatographically, collected and purified by repeated passage through 'Dowex-50' (NH_4-form).

The chromatographically pure serine was crystallized from a small volume of hot aqueous ethanol. Two crops were invariably obtained; the first crystallized easily on the addition of 2–3 volumes of ethanol to the aqueous solution, while the second usually required considerably higher ethanol concentrations, or the addition of ether, before crystallization occurred. 3 kgm. of frozen earthworms yielded 45 and 42 mgm. of the first and second crops, respectively. Both samples were shown to be pure serine by carbon, hydrogen and nitrogen analysis and by two-dimensional chromatography in ethanol/formic acid/water (7 : 1 : 2) and water-saturated phenol.

Examination of the optical rotation (in water) of the two samples showed crop 2 to be lævorotatory, while crop 1 was optically inactive.

In order to exclude the possibility of racemization during extraction and subsequent fractionation, a sample of authentic L-serine was dissolved in 1·5 *N* perchloric acid and the entire isolation procedure repeated with this solution. The serine was recovered in good yield and crystallized. It was found to be lævorotatory ($[\alpha]^{22^\circ}_{D} = -7\cdot37$ in water, $C = 4\cdot2$ per cent).

The optical purity of the serine samples was checked using a partially purified D-amino-acid oxidase preparation[6] which also contained a very active catalase. With crop 1 the oxygen uptake in 3 hr. was 88 per cent of that theoretically expected (1·0 µatom/µmole) for DL-serine in the presence of catalase. No oxygen uptake occurred with crop 2 or with the control L-serine re-isolated by the standard procedure. The possibility that the D-serine found in the perchloric acid extract of the earthworms was due to racemization can thus be excluded. In this connexion Minthorn *et al.*[7] have also shown, using the two serine enantiomorphs labelled with carbon-14, that the optical purity of serine was unaffected by techniques similar to those employed in the present experiments. Differential crystallization of DL-serine and one of the optically active enantiomorphs from a mixture has also been reported by these workers[8].

The present results thus establish the occurrence of D-serine in the free amino-acid pool of the earthworm, and, in view of the almost total recovery of the serine contained in the original extract, suggest that about 25 per cent of the free serine present is of the D-configuration. To the best of our knowledge this is the first occasion on which a free D-amino-acid has been unequivocally shown to be present in animal tissue. However, two unconfirmed early reports, on the finding of D-ornithine in fish liver[9], and of DL-alanine and DL-glutamate in goose and insect tissues, respectively[10], are referred to by Neuberger[11].

It would seem likely from the present findings that, in the earthworm, serine ethanolamine phosphodiester, and therefore lombricine, is synthesized from D-serine drawn selectively from the amino-acid pool.

A full account of this work will be published elsewhere.

Attachment of Immature Simuliidae to other Arthropods

AMONG biting flies of the family Simuliidae there are several species which, in their early stages, live in a remarkable association with other animals[1,2]. The larvæ and pupæ of the *Simulium neavei* complex, which includes an important vector of human onchocerciasis, are attached to freshwater crabs, and those of the *S. copleyi* complex to mayfly larvæ. The study of the association was interrupted by the extermination of *S. neavei* in a large area of Kenya[3], and the place of oviposition, the way in which the larvæ find their hosts, and the exact effect of the phenomenon are not yet known. The interest of the association is enhanced by its wide distribution; the *S. neavei* complex is represented in the Cameroons Republic[4] as well as in eastern and central Africa, and an unrelated species is associated with mayfly larvæ in the U.S.S.R.[5]. We now record the finding of Simuliids on dragonfly larvæ.

In January about forty crabs were examined near Salisbury, Southern Rhodesia, for larvæ of the *S. neavei* complex but without success. Seven dragonfly larvæ were collected in the Unwindsi stream, and a patch of Simuliid eggs was found on the abdomen, just behind the wing pads, of one of them which was 36 mm. long and belonged to a species of *Aeshna*, probably *rileyi* Calvert. The three hundred or so yellow eggs were placed in a wet tube and they hatched three days later after a journey by air. In the same district a small Simuliid larva was found on the side of a crab in the Ruwa stream. The hypostomium of this larva and first-stage larvæ from the eggs had three prominent apical teeth and was quite unlike that of the *S. neavei* complex, but resembled that of *S. lumbwanus* De Meillon. This character, combined with the presence of ventral papillæ, showed that the larvæ could be *S. adersi* Pomeroy, which was found in the larval stage on stones in the same stream, has a wide range of breeding places, and is probably related to the *S. neavei* complex. Two larvæ of another species, *S. medusaeforme* form *hargreavesi* Gibbins, probably in the third stage, were seen on the frons and the left wing pad of an 18 mm. Libellulid dragonfly larva which was found among a dense mass of these larvæ in the River Parmasea near Lokoja in Nigeria in August

1959. Other larvæ were found in similar circumstances in the River Hawal in the same country.

It seems unlikely that the eggs were laid on the larva by chance; but the significance of their presence is unknown. The finding on aquatic animals of larvæ of two species, at least one of which is outside the *S. neavei* complex and normally attaches itself to inanimate objects, may indicate how the Simuliid–crab association arose. Possibly larvæ attached themselves to crabs, received protection from certain natural hazards, and gave rise to a form which always behaved in this way. Whatever the reason for the findings, they suggest that it would be worth while to examine dragonfly larvæ and other aquatic animals in various parts of Africa and elsewhere in the hope of gaining more information about the association of immature Simuliids with larger animals. Young larvæ should, if possible, be kept alive in running water until they are large enough to be identified.

We are grateful to Mr. D. E. Kimmins of the British Museum (Natural History) for examining the dragonfly larvæ.

Inhibition of Nodule Bacteria by an Antibiotic from Legume Seed Coats

THE loss of viability of *Rhizobia* on the surface of some legume seeds was described in early reports quoted by Fred, Baldwin and McCoy[1] and more recently by other workers. Greenwood (personal communication) found that survival of *Rhizobia* was better when applied in a peat-pumice carrier than in a milk suspension, and suggested that the white clover (*Trifolium repens*) "seed surface may have a toxic effect on rhizobia". Vincent[2] showed that survival on glass beads was superior to that on subterranean clover (*T. subterraneum*) seed. Lobb[3] suggested that an inhibitory substance may be present in lucerne (*Medicago sativa*) and white clover seed coats. However, in no case was it conclusively demonstrated whether reduced viability was due only to unsuitable physical conditions for survival or also to an inhibitory effect of the seed. Inhibition of organisms other than *Rhizobia*, by antibiotic substances in the seed of flowering plants, has been demonstrated by several workers[4-6].

Table 1. INHIBITION OF *Rhizobium trifolii* STRAIN *TA*1 ON PLATES BY SEED AND SEED EXTRACTS OF *Trifolium subterraneum* L. VAR. TALLAROOK

Seed treatment	Inhibition zones Mean distance – seed edge to zone edge (mm.)
Untreated	4·1
Autoclaved	4·7
Soaked and dried	0·1 *l.s.d.* 5 per cent = 3·4
Soaked, dried, and autoclaved	0·6
Autoclaved, soaked and dried	0·9
Autoclaved, soaked, dried and autoclaved	0·3
Source and treatment of water extract absorbed by filter paper disks	**Mean distance – disk edge to zone edge (mm.)**
Control—no extract	0·0
Extract of untreated seed	6·8
Extract of autoclaved seed	5·2 *l.s.d.* 5 per cent = 3·4
Extract of untreated seed autoclaved after absorption	4·0

Preliminary investigations showed that untreated and autoclaved seed of subterranean clover, and their extracts, inhibited *Rhizobia* in culture, but soaked seed did not. The following experiment was then carried out, using the direct plate method for testing seed[7] and the filter paper disk method for testing extracts[8].

Seed and seed extracts of *Trifolium subterraneum* L. var. Tallarook were treated as listed in Table 1. For soaking, 20 seeds were placed in 10 ml. of distilled water for 6 hr. This water was replaced with 10 ml. for a further 1 hr. before being poured off and the seed dried. Seed extracts were obtained by soaking 400 seeds in 10 ml. sterile water for 7 hr. Sterile filter paper disks (5 mm. diam.) were then immersed for 1 min., removed and dried. Disks were treated 3 times. Seed and filter paper disks were dried, at 50° C. in a sterile oven, to minimize variations between treatments due to differential uptake and loss of water during preparation of the treatments. Autoclaving of seed and extracts (15 lb. per sq. in. for 20 min.) prevented germination of seed, and antibiotic production by seed-borne organisms. Seed soaking and autoclaving treatments were combined to test whether any antibiotic from autoclaved seed formed only as a result of autoclaving was extractable, and, if so, whether it affected *Rhizobia* similarly to that from untreated seed.

Petri dishes, each containing 20 ml. of 1·4 per cent yeast mannitol agar, were surface inoculated with a suspension of 5×10^8 organisms (*Rhizobium trifolii* strain *TA*1). Three seeds or disks of each treatment were placed on the agar surface of each of 3 plates. Inhibition measurements were made after 93 hr. incubation at 27° C.

Inhibition was indicated by a clear zone, containing no visible colonies, surrounded by a zone of reduced colony size and number. Beyond these zones *Rhizobium* growth appeared normal. The distance of seed or disk edge to the zone of normal growth was measured.

Untreated seed was inhibitory. With soaked seed inhibition zones were very small but a seed extract strongly inhibited growth. Autoclaving of seed did not significantly affect the strength of inhibition whether the seed had been previously soaked or not, showing that no secondary inhibitory substances were formed due to autoclaving. Similarly autoclaving of the seed extract did not affect inhibition. The inhibitory substance in autoclaved seed was extractable with water and the extract of untreated seed retained its activity after autoclaving.

Further investigations showed that the antibiotic was associated with, and extractable from, the seed coat and not the embryo. Contrary to Ferenczy's findings[8], germination was not necessary for antibiotic production. In fact, recolonization of the inhibited zone was more rapid with viable germinating seeds than with autoclaved seeds.

Some variation occurred between individual seeds but variation between species was more marked. Autoclaved seed of three separate samples of three forage legume species were tested with *Rhizobium trifolii* strain *TA*1. Inhibition was strong with subterranean clover (mean 5·8 mm.), considerably less with white clover (1·5 mm.), and weak with lucerne (0·3 mm.). Differences in seed size do not adequately explain these differences, as lucerne seed is larger than that of white clover.

Field evidence, suggesting the presence in subterranean clover seed of substances inhibitory to *Rhizobia*, has been obtained at this laboratory. Spencer (personal communication) found that soaking of seed prior to inoculation and sowing resulted in greatly improved nodulation from the applied inoculum. On the other hand, when inoculum was applied to the soil there was no beneficial effect of soaking seed. I have found that physical separation of the seed coat and inoculum, by coating the seed with inert material before inoculation, improved nodulation of subterranean clover.

The results presented indicate that the seed coats of the subterranean clover investigated contain a thermo-stable, water-soluble antibiotic, active against a strain of *Rhizobium* normally incorporated in commercially prepared inocula. This substance could contribute to loss of viability of nodule bacteria on the seed both in storage and in field sowings.

Effect of Autumn Applications of Potassium Gibberellate on Fruit Production of the Strawberry

In the autumn of 1957 at New Brunswick, New Jersey, single-row, 30-ft. replicated plots of Sparkle strawberries were treated with 20 and 50 p.p.m. of potassium gibberellate. Three applications were made, with the first application applied on September 13. An additional variable was added by using both a 1-week and 2-week interval between spray applications. No effect was noted in the autumn of 1957 from these sprays except for an occasional inflorescence observed on the plots sprayed with 50 p.p.m. The next spring the sprayed plots had a heavier bloom early in the flowering period as compared with the unsprayed plots. The harvest records for 1958 showed that the treated plots produced about a 30 per cent larger volume of early fruit than the unsprayed checks, with no difference due to interval between spray applications. Due to rains and fruit rots during the latter part of the 1958 harvest season, total yield records were not recorded.

In the autumn of 1958 another investigation was conducted using 30-ft. single-row plots of Sparkle strawberry plants. Each treatment was replicated five times. Treatments consisted of 0, 10, 20, 30, 40, 50 and 100 p.p.m. of potassium gibberellate (supplied by Merck and Co., Rahway, New Jersey, which supported this work with a grant-in-aid) applied as sprays on September 17, October 1 and October 15. Some inflorescences were observed later in the autumn on plots sprayed with 40, 50 and 100 p.p.m., and petiole elongation was observed at the 100 p.p.m. level.

Table 1. Effect of Potassium Gibberellate Sprays on Yield of Sparkle Strawberry Fruit

Spray concentration (p.p.m.)	Yields	
	Early harvest* (quarts/acre)	Total† (quarts/acre)
0	2,603	10,662
10	3,758	9,519
20	3,616	8,637
30	3,515	8,252
40	2,485	5,209
50	2,390	5,241
100	822	1,678
L.S.D. 0·05	958	1,882
L.S.D. 0·01	1,298	2,550

* Includes harvests of May 28, June 2 and June 5.
† Total yield was based on above three harvests plus an additional five completed by June 26, 1959.

The results obtained in the 1959 harvest season (Table 1) indicate that by June 5 (including three harvests) the 10 and 20 p.p.m. treatments had significantly increased the volume of fruit harvested as compared with the unsprayed checks: the 100 p.p.m. treatment, on the other hand, had significantly reduced yields. The total yields (including eight harvests) for these plots showed that there was no significant difference between the unsprayed checks and the 10 p.p.m. treatment, while all the other treatments showed a significant reduction in yield.

The application of three sprays of 10 p.p.m. of potassium gibberellate in the autumn may give the strawberry grower an economic advantage, since the early fresh market fruit commands a premium price.

Viability and Germination Inhibitor of the Seed of Rice

The loss of viability of seeds within one year after harvesting has been reported by Grist[1] from varieties of rice grown in British Guiana and by Ramiah[2] in India, but no explanation has been offered. Germination tests of a winter variety 'Rupsail' recently carried out in this laboratory indicated peak germination

during March–June following harvesting in December; thereafter it declined and from November onwards the viability was lost. Seeds harvested in 1953 and 1957 failed to germinate in 1959. The excised embryos from fresh seeds of 1958 germinated only in White's nutrient agar media while those of one- or five-year old seeds did not grow. Respiration-rates measured by Warburg apparatus indicated higher rates in fresh seeds than the old ones (Table 1).

The results thus show that the failure of germination of old seeds of 1953 and 1957 is not due to the nature of the husk acting as a barrier with increasing carbon dioxide concentration inside or the old seeds becoming dead. The possibility of the presence of germination inhibitor and its formation was then investigated.

Tests were made on the basis that the inhibitor, if present, might be leached out of the seeds during soaking in water for 24 hr. Leachings from seeds of 1953, 1957 and 1958 were therefore used for the growth of viable seeds; 88–90 per cent seeds just sprouted but subsequent growth of root was inhibited in the leachings from the non-viable seeds of 1953 and 1957 and shoot growth accelerated in later periods (Table 2). Promotion of growth of the shoot and inhibition of growth of the root are suggestive of auxin action. Auxin assay of the embryo extracts by root inhibition tests showed that embryos from old seeds contained a higher amount of indoleacetic acid equivalent in comparison to that of viable seeds. The concentration was much increased in the embryos of 5-year-old seeds. From consideration of the presence of a large amount of auxin in the embryos of non-viable seeds and reduction of embryonic root growth in the leachings, it is presumed that there exists a close relation between auxin concentration and the formation of germination inhibitor.

Experiments performed on the effects of different light qualities indicated that white light increased germination over the percentage in the dark. But the percentage in red was not increased over darkness while far-red rays had the largest inhibiting effect (Table 3). In photoblastic seeds Toole *et al.*[3] have recorded stimulation in red over darkness, but infra-red following red inhibited germination. Inhibiting effect in rice seed was further shown when red was interpolated between white light and dark as the percentage of germination was considerably reduced in comparison with treatments of light and dark. It appears that the absorption of red and far-red rays leads to the formation of germination inhibitor in rice seeds.

We thank Miss Protima Datta Ray for assistance in the measurement of respiration-rates.

Foliar Application of Nutrients and Rhizosphere Microflora of *Camellia sinensis*

SUSCEPTIBILITY of plants to fungi causing root-rot is known to be conditioned by the rhizosphere microflora[1,2]. Changes in this microflora can result from derangement in plant metabolism caused by either foliar treatment with chemicals[3], fungal infection of the roots[2] or even systemic infection by plant viruses[4]. Therefore, it seems possible to stimulate artificially the multiplication of specific micro-organisms in the rhizosphere by selective plant treatment, such as foliar application of nutrients, designed to act directly on the plant without affecting the soil. Work on these lines, apart from a recent report[5], has received little attention. Observations on sprayed tea plants reported here support the basic concept of changing the pattern of the rhizosphere microflora by foliar sprays.

One-year-old monoclonal selections of tea plant, propagated from cuttings, were grown in tea field soil in earthenware pots, and each experimental plant was sprayed with an atomizer with 10 ml. aliquots of nutrient solutions (Table 1). Distilled-water sprayed plants formed controls. The soil was protected from run-off spray by a plastic cover. The plants were kept under a bell-jar for 24 hr. after each spray application, four of which were made at 2-day intervals. Four days after the completion of the last spray, rhizosphere soil from each treatment (three replicates) was sampled and dilutions plated in soil-extract, glucose, nitrate-agar for bacterial, and in peptone, dextrose-agar containing 1 : 10,000 crystal violet and 15 μgm./ml. each of streptomycin and dihydrostreptomycin for fungal, counts.

Table 1

Foliar spray treatments	Rhizosphere population in 1 gm. dry soil		
	Fungi (in thousands)	Bacteria (in hundred thousands)	Fungal genera and species occurring in the rhizosphere
(*A*) 0·76 *M* $(NH_4)_2SO_4$	125·0	32·3	(1), (2)*
(*B*) 0·04 *M* $MgSO_4.7H_2O$	93·5	12·3	
(*C*) 0·67 *M* KCl	256·5	27·0	(2)
(*D*) 1·47 *M* $NaNO_3$	176·5	33·0	(2)
(*E*) 0·28 *M* $Na_2HPO_4.12H_2O$	281·5	14·0	(2), (3)
(*F*) 0·83 *M* Urea	73·5	20·3	(1)
(*G*) Control: distilled water	193·5	44·0	(2)
Difference required for significance, *P* = 0·01	32·0 FBADGCE	6·3 BEFCADG	

* (1) *Stysanus* sp., (2) *Scopulariopsis brevicaulis* Bain., (3) *Myrothecium* sp.

Foliar spray with any of the inorganic or organic nutrients significantly reduced the bacterial population of the rhizosphere soil (Table 1). 0·67 *M* solution of potassium chloride and 0·28 *M* disodium hydrogen phosphate significantly increased the number of fungi in the rhizosphere soil over that in the control, whereas a significant reduction of fungal numbers was recorded with application of 0·04 *M* magnesium sulphate. The rhizosphere fungi responded differently to spray containing comparable amounts of nitrogen but from different nitrogen sources. With 1·47 *M* solution of sodium nitrate there was no significant difference in fungal numbers over control plants, but spraying with 0·76 *M* ammonium sulphate and 0·83 *M* urea significantly decreased the fungal population. Although spray application with urea markedly increased fungal population in the rhizosphere of rice plants[4], the reverse seems to be the case in tea plants.

Table 1 also summarizes specific differences in the genera and species of fungi occurring in the rhizosphere of plants sprayed with different nutrilites. Such differences in the occurrence of a species of *Penicillium* in the rhizosphere of urea-sprayed rice plants has recently been reported[5]. Roots of plants subjected to high temperature, high light intensity[6] or desiccation[7] are known to exude large amounts of amino-acids and these energy sources are presumed to be used up by micro-organisms[6]. Differences in the rhizosphere microflora resulting from foliar application of nutrients is probably due to qualitative and quantitative changes in the root exudates induced by the plant treatment. Further work on these lines is in progress and details will be published elsewhere.

I thank Prof. T. S. Sadasivan for helpful suggestions, the Director of the Commonwealth Mycological Institute, for identification of fungal cultures and the Chief Scientific Officer of this Department for facilities to carry out this investigation.

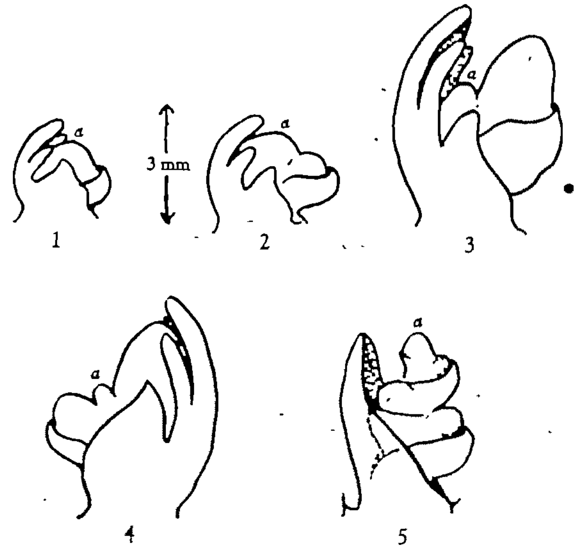
Axial Origin of the Terminal Inflorescence in the Genus *Trifolium*

J. L. STODDART[1] states that floral initiation in red clover begins by the enlargement of the shoot apex. The following observations show that the actual shoot apex is absorbed by an adjoining lateral bud. The origin of the terminal inflorescence of this species as a lateral bud is therefore similar to that of the axillary inflorescence in other species.

In species with axillary inflorescences (for example, *T. subterraneum*[4] and *T. repens*), the change from the vegetative state (Fig. 1) to the reproductive begins at the shoot apex (*a*) with the formation of a bulge in the axil of the topmost leaf initial (Fig. 2). A similar bulge is formed in each further leaf initial, the bulge and leaf initial developing into the type of inflorescence and leaf typical of the species, and the tissue expanding between each leaf to make the lengthened internodes characteristic of the flowering stage of the shoot.



In species with terminal inflorescences (for example, *T. pratense* and *T. alexandrinum*), the reproductive state begins in the same way, but is followed by domination and absorption of the shoot apex by the first one or two lateral bulges. Usually the first bulge is the only one; it increases in size (Fig. 3) until the shoot apex disappears. Florets are differentiated from a series of small bulges formed over its surface. Sometimes a second bulge is formed in the axil of another leaf initial before the shoot apex stops growth. In this case, the apex can be seen for a short time between the two enlarging inflorescence primordia (Fig. 4). The younger inflorescence is usually the smaller of the two when fully developed.

It is interesting to note that the terminal inflorescences of well-known gramineous genera also originate from lateral bulges in leaf initials close to the shoot apex (for example, oat, Fig. 5). Apart from differences in floret structure peculiar to each family, the mature inflorescence of a grass or cereal therefore differs from that of a clover mainly by the number of 'fertile' leaf initials, and by the development of each such leaf initial to form a small ridge only instead of a leaf (for example, *Avena sativa*[2] and *Lolium perenne*[3]).

BACTERIOLOGY

A Growth Factor for *Haemophilus* Species secreted by a Pseudomonad

THE clustering of bacterial colonies of one species around those of another—satellitism—was first described for *Haemophilus influenzae* by Grassberger in 1897[1]. The interrelationship is probably due to the supply of critical nutrients by one micro-organism to the other. While the special nutritional requirements of *Haemophilus* species have been studied and some compounds essential for growth identified[2], the nature of bacterial substances responsible for the satellite phenomenon have not been investigated. In this communication we report on the isolation of such substances.

It is much easier to study excretory products of bacteria in a chemically defined medium than in a complex one. Therefore, only cultures able to grow in simple media were screened for their ability to stimulate growth of *Haemophili* on blood agar or support it on brain heart infusion (Difco Laboratories, Detroit) agar. Test organisms included seven strains of *Haemophilus* of animal origin, four strains of *H. influenzae*, and one strain each of *H. parainfluenzae*, *H. parahaemolyticus* and *H. gallinarum*. The cultures were streaked on test media and crossed with a single streak of the possible 'feeder'. A good 'feeder' was found to be a pseudomonad isolated from an emperor penguin and obtained from Dr. L. A. Page. This bacterium grew well in a solution of histidine (200 mgm. per cent), monobasic potassium phosphate (20 mgm. per cent), mineral mix No. 49 (supplied by Dr. J. H. Hunter, Haskins Laboratories, New York, and containing iron, manganese, zinc, cobalt, copper, vanadium and boron) (8 mgm. per cent) at *p*H 7·5 and 37° C. When grown in such a medium, the organism secreted growth factors essential for *Haemophilus* species, apparently the same as produced in the more complex media.

The penguin pseudomonad was grown in 1 litre of the above medium for 48 hr. After the cells had been removed by centrifugation, the supernatant was Seitz-filtered and lyophilized. The dried material was redissolved in 10 ml. of water and chromatographed, using ascending chromatography with a solvent system consisting of butanol, acetic acid, and water (4 : 1 : 5). Two ultra-violet-absorbing spots were observed under illumination with a 'Mineralight' (2537 *A*) (Ultra-violet Products, Inc., South Pasadena), of which one was much denser than the other. An additional spot was detected after spraying with ninhydrin—probably histidine from the growth medium, as shown by a reference sample.

The ultra-violet-absorbing material (*EP*) contained in the denser spot was eluted from the paper and added to brain heart infusion agar. This medium could then support the growth of *Haemophili*. *EP* was further purified by repeated partition on Whatman No. 1 filter paper and subsequent elution. The solvents, used in sequence, were: monobasic sodium phosphate, 5 per cent; *iso*propanol, ethanol, and water in the ratio of 7 : 2 : 1; and *iso*propanol and 0·2 *M* ammonium hydroxide in the ratio of 3 : 1. Prior to use, the filter paper had been washed for 24 hr. in distilled water.

Purified *EP* had ultra-violet absorption optima at 265 and 275 mμ at *p*H 1·0 and 11·0, respectively. On hydrolysis, with 2 *N* hydrochloric acid at 115° C. for 60 min., a carbohydrate was released which, in three different solvents, had the same R_F as ribose. *EP* was found to be free of phosphorus. In aqueous solution it could be heated at 100° C. for 30 min. and 120° C. for 5 min. without substantial loss of activity; heating at 120° C. for 10 min. resulted in complete inactivation.

Species of *Haemophilus* require for growth either *V* factor—replaceable with diphosphopyridine nucleotide, or its nucleoside[3]—*X* factor—replaceable with hæm, or both. Since most of our animal strains which were stimulated by *EP* showed no hæm requirement, a relationship between *EP* and diphosphopyridine nucleotide was suggested. *EP*, both before and after acid hydrolysis, had a different R_F value from niacin, niacinamide, niacinamide riboside, niacinamide mononucleotide, and diphosphopyridine nucleotide. It also differed from these in ultra-violet absorption spectra. Infra-red absorption spectra do not exclude *EP* from being a derivative of niacinamide.

EP could be replaced as a growth factor for *Haemophilus* by diphosphopyridine nucleotide and niacinamide mononucleotide but not by niacinamide, adenosine triphosphate or the products of acid hydrolysis of ribo- or deoxyribo-nucleic acids. Test organisms grew in brain heart infusion broth with either niacinamide mononucleotide or diphosphopyridine nucleotide in the concentration of 10γ per cent, whereas *EP* was required at the concentration of 1,000γ per cent. While it is possible that this amount reflects the true needs of the test species, the possibility of partial inactivation of the compound during the purification process cannot be disregarded. Dorfman *et al.*[4], working with *Shigella*—which requires nicotinic acid or niacinamide for growth—showed that N-substituents of niacinamide served as growth factors while substitution on the ring inactivated the molecule. In one case where quinolinic acid could be used to promote some growth, its effective concentration was 1,000 times that of niacinamide.

While the data on hand are insufficient to characterize *EP* completely, present information suggests that it might be a niacinamide riboside with unknown substitutions. Its implied biological significance would be consistent with such an interpretation. Work to elucidate further the structure and composition of *EP* is in progress.

This work was supported in part by a U.S. Public Health Service grant *E*–1726.

Antibody Responses of the Domestic Fowl to Two Soluble Bacterial Antigens

FOR some years now virologists have recognized the value of the domestic fowl as a means of obtaining high-titred antisera to viral and rickettsial antigens. Bacteriologists and immunologists have almost invariably preferred the rabbit, consequently little information is available about the responses of fowls to soluble bacterial antigens. While investigating the immunological tolerance of diphtheria alum-precipitated toxoid in the domestic fowl[1] I had the opportunity of collecting a limited amount of information about the primary and secondary antibody responses of White Leghorn fowls to both tetanus alum-precipitated toxoid (Wellcome series *W6874A*) and diphtheria alum-precipitated toxoid (Wellcome series *BA6403A*); though only one dosage of each antigen was used, the results may be of value to other workers.

Twenty birds between the ages of 10 and 14 months were used in the experiment. One group of ten was given a primary stimulus of 1·0 ml. diphtheria alum-precipitated toxoid (20L_f) intramuscularly; the other received 1·0 ml. tetanus alum-precipitated toxoid (50L_f) by a similar route. A sample of blood was taken from each bird immediately before primary challenge and then at 3- or 4-day intervals for 31 days. A second dose (1·0 ml.) of the respective antigens was given intramuscularly 34 days after the last bleeding (that is, 65 days after primary challenge). The fowls were bled immediately before this injection and then at intervals of 2 or 3 days for the next 15 days.

The serum was separated from these blood samples by centrifugation and the appropriate samples tested for their diphtheria antitoxin content (Romer and Sames[2], as modified by Glenny and Llewellyn-Jones[3]), or their tetanus antitoxin content[4].

Fig. 1 shows the average primary and secondary antibody response of ten fowls to diphtheria alum-precipitated toxoid. Antibody to this antigen was first detected 10 days after primary stimulation, reached a maximum in most cases on the fourteenth day and then gradually declined. After secondary stimulation, antibody was always detectable after 3 days and reached maximum concentration between the eighth and thirteenth day, the tenth day after injection being the most usual.

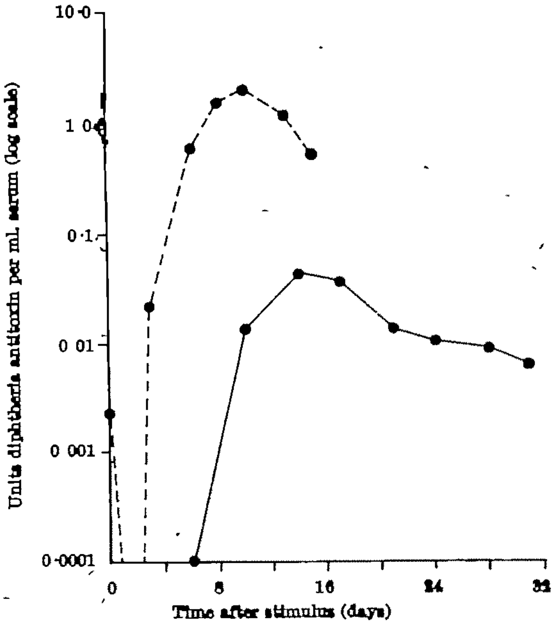

Fig. 1. Average antibody responses of 10 birds to the primary (●—●) and secondary (●– – –●) antigenic stimulus with diphtheria alum-precipitated toxoid

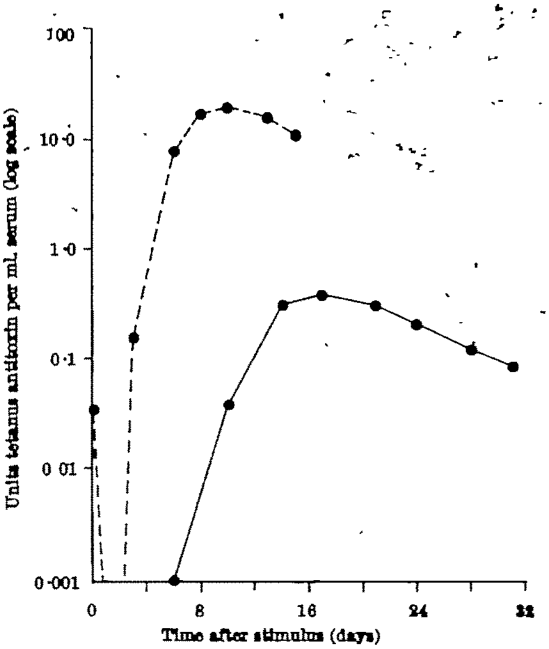

Fig. 2. Average antibody responses of 10 birds to the primary (●—●) and secondary (●– – –●) antigenic stimulus with tetanus alum-precipitated toxoid

Fig. 2 shows the primary and secondary antibody responses to tetanus alum-precipitated toxoid. These responses are similar in form to those with diphtheria alum-precipitated toxoid as the antigen, except that the maximum response to primary challenge with tetanus alum-precipitated toxoid appears to be delayed for about three days and is therefore not usually reached until the seventeenth day. This finding was general among the group.

The individual maximum antibody concentrations reached were 0·1 I.U. diphtheria antitoxin and 3·0 I.U. tetanus antitoxin per ml. of serum during the primary response, and during the secondary response 5·0 I.U. diphtheria antitoxin and 65 I.U. tetanus antitoxin. There was, of course, considerable individual variation in the amounts of antibody produced, but, as can be seen from the figures, the antibody responses in these birds compare favourably with those obtainable in the rabbit under similar conditions.

A number of fowls were also injected with both antigens simultaneously[1], one antigen being injected into each leg. Results similar to those described above were obtained and there was no evidence of any interference between the two antigens.

FORTHCOMING EVENTS

Tuesday, August 16

Institute of Metals (at 17 Belgrave Square, London, S.W.1), at 6.30 p.m.—Dr. J. J. Gilman: "The Physical Nature of Plastic Flow".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Assistant Librarian (with a university degree)—The Secretary, The University, Aberdeen (August 20).

Radio Propagation Engineer (with an appropriate university degree with honours or equivalent, and experience in radio propagation research and meteorological physics) at the Research Laboratories, Australian Post Office, Melbourne, for the scientific investigation of tropospheric radio propagation as related to general meteorological phenomena—The Australian Post Office Representative, Australia House, Strand, London, W.C.2 (August 20).

Research Assistant, to perform theoretical investigations on various aspects of semiconductors—Prof. P. T. Landsberg, Department of Applied Mathematics, University College, Cathays Park, Cardiff (August 20).

University Demonstrator in the Department of Veterinary Clinical Studies, to assist in the teaching of clinical pathology—Dr. G. A. Gresham, The Medical School, The University, Tennis Court Road, Cambridge (August 25).

Senior Lecturer in Mathematics; and a Senior Lecturer in Mathematical Statistics at the University of Adelaide, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, August 31).

Research Assistant (Plant Biochemist) to Dr. B. T. Cromwell, for work on biosynthesis of alkaloids in higher plants—The Registrar, The University, Hull (September 3).

Lecturer (Electron Microscopy), for integrated biochemical and cytological studies of cell division; and a Lecturer (Physical Biochemistry), for studies of proteins, particularly of wheat grain, in the Department of Agricultural Chemistry at the Waite Agricultural Research Institute, University of Adelaide, Australia, —The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, September 5).

Botanist, Scientific Officer grade (with a good honours degree and preferably postgraduate training or research experience), to study the development and anatomy of apples in relation to storage behaviour—The Secretary, East Malling Research Station, near Maidstone, Kent (September 7).

Lecturer (graduate in civil, mechanical or electrical engineering) in Engineering; and a Lecturer in Geology at Fourah Bay College, The University College of Sierra Leone—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (September 15).

Lecturer/Senior Lecturer (qualified in grassland management) in Animal Husbandry at the University of Sydney Animal Husbandry Farms, Camden, New South Wales, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, September 15).

Research Biophysicist (with a degree in medicine or biology, previous research experience, and preferably experience in the technique of electron-microscopy), to undertake an investigation into some aspects of industrial chest disease with special reference to asbestos, and to work either in the Department of Pathology or in the Cavendish Laboratory, or partly in both Departments—The Secretary of the Department of Physics, The Cavendish Laboratory, The University, Cambridge (September 15).

Senior Lecturer and Director (with high academic qualifications and experience of high-speed digital computers) of the Sub-Department of Computation—The Secretary and Registrar, The University, Southampton (September 15).

Lecturer/Senior Lecturer and a Lecturer in Psychology at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, September 16).

Chair of Psychological Medicine—The Secretary, The University, Edinburgh (September 23).

Chair of Botany in the University of the Witwatersrand, Johannesburg, South Africa—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (South Africa and London, September 30).

Reader in Mathematics—Prof. Titchmarsh, Mathematical Institute, The University, Oxford (October 15).

Scientific Officer (honours graduate, preferably with two to three years postgraduate experience) in the Entomology Department—The Secretary, Rothamsted Experimental Station, Harpenden, Herts (October 15).

Assistant, Grade B, in the Architecture and Building Department, to teach Mathematics to G.C.E. "A" level standard to full-time students in the Land Surveying Section—The Clerk to the Governors, South-West Essex Technical College and School of Art, Forest Road, Walthamstow, London, E.17.

Assistant Principal (with a university degree in forestry and preferably experience in teaching and tropical forestry) of the Forest School, Uganda—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD.61/9/08/01.

Education Officer (with a university degree or equivalent qualification and several years experience in a special library or information department, preferably in industry), to make a special study of the training requirements of special librarians and information officers and to organize frequent short courses in this field)—The Director, Aslib, 3 Belgrave Square, London, S.W.1.

Field Seismologist (with an honours degree in mathematics and physics, geophysics or a closely related science, plus experience in seismological field work) in the Department of Mines and Technical Surveys, Canada, to direct a group conducting long-range seismic observations on the Polar Continental Shelf and at sea with the most modern magnetic tape equipment—Dept. 1510, National Employment Service of Canada, 61 Green Street, London, W.1.

Game Officer (male, with a university degree in zoology) in Kenya, initially for normal Game Warden duties, but after experience of Kenya conditions, for research work—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD.152/7/04.

Graduate Research Assistant in Physics, to work on studies of the structure of diamonds by optical methods—The Principal, Royal Holloway College (University of London), Englefield Green, Surrey.

Lecturer (with a degree in electrical engineering and appropriate professional qualifications, with teaching and industrial or research experience) in Electrical Engineering—The Principal, Kingston Technical College, Fassett Road, Kingston-upon-Thames, Surrey.

Lecturers (2) in Zoology, one to teach histology and microtechnique, and the other to teach ornithology (and, if possible, animal behaviour)—MacGill University, Montreal, Quebec, Canada.

Meteorologists (men or women, with a good honours degree in mathematics and/or physics, and preferably experience in a meteorological service, especially in analysis and forecasting) in the East African Meteorological Department, for duties which may include weather analysis and forecasting (including research); consultative meteorological work related to agriculture, hydrology, etc.; research into climatology, rain stimulation, evaporation control, and work in the field of geomagnetism or solar radiation—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD.57/88/01/C1.

Professor of Physiology, and a Professor of Biochemistry at the University of Shiraz, Iran—The Director, Recruitment-Department, British Council, 65 Davies Street, London, W.1, quoting N.12/T (60).

Research Assistant (preferably with an honours degree, some experience of vacuum techniques, electronics, or a knowledge of dielectrics) in Physics in the Department of Natural Philosophy, for work on the properties of thin dielectric films—The Secretary, Royal College of Science and Technology, George Street, Glasgow, C.1.

Research Workers (2) (with an honours degree in biochemistry or zoology, and preferably with previous research experience) in the Department of Zoology, for the extension of fundamental work now in progress on (*a*) the mode of action of insecticides and (*b*) chemoreception of insects—Dr. A. B. P. Page, Imperial College Field Station, Ashurst Lodge, Sunninghill, Ascot, Berks.

Rexco Research and Development Company Research Students (with, or anticipating to have, a good honours degree in chemistry, Grad.R.I.C., or a Dip.Tech. in pure or applied chemistry), for the study of products from the low temperature carbonization of coal—Head of the Department of Applied Chemistry, Northampton College of Advanced Technology, St. John Street, London, E.C.1.

Scientific Officers or Senior Scientific Officers (with a first- or second-class honours degree in an appropriate subject or equivalent) at Home Office Forensic Science Laboratories at Cardiff (Chemist), Preston (Chemist and Biologist) and Birmingham (Chemist or Biologist), for examination of material received from police and to give evidence in criminal courts—The Ministry of Labour, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting Ref. F.454/0A.

Senior Lecturer in Inorganic Chemistry; Lecturers (2) in Chemical Engineering; Lecturers (2) in Organic Chemistry; an Assistant, Grade B, in Applied Chemistry (Dyeing); and an Assistant, Grade B, in Metallurgy—The Registrar, Bradford Institute of Technology, Bradford 7.

Technical Officer (with a recognized degree or National Diploma in Agriculture, Horticulture or Agricultural Botany) in the Seed Production Branch, to specialize on root and vegetable seed crops—The Secretary, National Institute of Agricultural Botany, Huntingdon Road, Cambridge.

PHLOGISTON OR ATOMS?

WE hear a great deal these days about the need for more scientific and technological education, both to produce more scientists and technologists and to give the layman some idea of what they are doing; but the method adopted for this form of education is comparatively neglected. It seems to be assumed by too many people that the present school courses are quite adequate and that it is simply a matter of pushing more people through them. A report* by Dr. Michael Bassey, on a survey he carried out recently on what some arts students at the University of London remembered and thought of the chemistry they had learned at school, strongly suggests that there is something seriously wrong with elementary school chemistry, as presented to the person who does not intend to do any more science in any event; and what is true of chemistry is probably true of the other sciences.

One of Dr. Bassey's questions was: "Which of air, water, clay and wood contains atoms?" One in five got the answer wrong. A few of them may have thought he was trying to find out if they knew the difference between elements, compounds and mixtures; even so, the proportion is far too high. All the people questioned had passed at least chemistry in general science of the General Certificate of Education (Ordinary Level) and they were all university students. Elementary chemistry obviously cannot cover a great deal of ground, yet surely it should manage to instil the basis of all chemistry, that is, the atomic theory.

Since all the people who replied to the questionnaire had passed some form of chemistry (Ordinary Level), their ignorance cannot be due simply to inattention. What, then, were they doing during the years they studied chemistry? Another of Dr. Bassey's questions provides the answer: Were you taught about aspirin, DDT, Lavoisier, phlogiston and the Law of Multiple Proportions? In Dr. Bassey's own words: "Lavoisier came out top of the poll, phlogiston and the Law of Multiple Proportions shared the second place, and DDT and aspirin would have lost their deposits in a parliamentary election". In fact, the teaching of elementary chemistry is apparently dominated by a historical approach which tends to exclude modern developments.

It can, of course, be argued that in the short time available the historical approach will give the best understanding of the subject. The phlogiston theory is an excellent example of a hypothesis that fitted most of the facts available at the time. Lavoisier's experiments are probably the most important series in the whole history of chemistry. The determination of the composition of water does illustrate the sort of approach that is used in all the sciences. But to grasp the significance of such things requires a great deal of background knowledge which the ordinary schoolboy is certain not to possess, and a feat of historical imagination of which he is most unlikely to be capable. If he does not grasp their significance he feels that they are irrelevant and dull. A youngster who knows the formula of water is H_2O is apt to be contemptuous of anyone who does not.

What should elementary chemistry, or for that matter elementary science, try to do? Obviously it has to provide some sort of grounding: the scientific equivalents of addition, subtraction, multiplication and division. It should also create interest, in the sense that even someone who only intends to do science for a few years to pass the necessary examinations should be able to see why others should want to devote most of their time to it. But it is essential that it should not create the hostility that comes from boredom, and bored most of the people who replied to Dr. Bassey's questionnaire certainly seemed to have been. Most of them put this down to chemistry, as taught to them, being a lot of unconnected, uninteresting facts, totally unrelated to everyday life.

This is not really surprising when one considers the present syllabus. Its attempts to include everyday and commercial applications look as though they were put in fifty years ago, which they probably were. Washing soda! Bleaching powder! An obsolete process for manufacturing sulphuric acid! Most of the important developments in chemistry in the past twenty years or so have come from the organic field—plastics, drugs, insecticides—yet organic chemistry does not even appear in the Ordinary Level syllabus. One needs a certain amount of basic knowledge before starting organic chemistry, of course, but there might at least be some hint of the fact that carbon forms long chains and rings and that these are the basis of life. The real trouble with the historical approach is not that it is there, but that it seems to displace everything else.

The criticism that chemistry is taught as an unconnected series of facts is all the more regrettable, since it can be taught in a way that makes it a coherent body of knowledge, developing logically from a few basic ideas, leading straight to many interesting and stimulating modern developments, and emphasizing the close connexion between chemistry and physics. The way is simply to start with the atom. The structure of the atom leads naturally to the periodic classification of the elements, and here some properties of the elements can be introduced not as isolated facts but to show how the elements are related to one another. Valency follows from atomic structure. Ionization, crystals, states of matter, can all be dealt with in terms of the atom. In fact, the whole subject can be brought together, and at each point items of everyday and topical interest can be introduced—the new metals, atomic energy, rocket fuels—things that stimulate interest instead of killing it.

---

* *New Scientist*, 7, 1594 (1960).

The atomic theory can be expressed quite easily in simple terms; so there is really no justification for saying that it is too advanced to be understood by children in their early teens. After all, the study of electricity nearly always begins with electrostatic attraction. The force that attracts the electrons to the nucleus can be demonstrated with a fountain pen rubbed on the sleeve and a bit of paper. There is the analogy with the solar system, and atomic structure lends itself very well to demonstration by diagrams and models. It is certainly a good deal easier to understand the elementary theory of the atom than to grasp the significance of the phlogiston theory.

Dr. Bassey's questionnaire was sent to arts students; but these arguments apply equally well in the case of people who intend to specialize in science. The fact that they have an interest in science is no excuse for a boring syllabus. The defects in school chemistry are particularly obvious at the elementary stage, but they persist right through the school. Is there any real justification for the amount of time devoted to the extraction of metals at General Certificate of Education (Advanced Level), for example? A good deal of irrelevant material could probably be found in university courses as well.

The teachers cannot be blamed for this state of affairs, although most people are reluctant to change a well-established routine, since they have to prepare their pupils for examinations based on an out-of-date syllabus. But they are represented on the committees that decide what shall be included, so they do have an opportunity to try to improve things. Books, too, tend to be written around a syllabus. In fact, there are a lot of vested interests that will probably oppose any far-reaching changes, and far-reaching changes are certainly due.

Every year there is more and more to be learned; if the new things are not to be neglected, as they tend to be at present, a continuing review of examination syllabuses will be necessary, to prune off things that have lost their importance. If no pruning is done the syllabus will grow so fast that it will soon become quite unrealistic. The historical approach should not be dropped automatically; in many cases it may be very suitable, but the question, "What is the best approach?", should always be asked before any approach is adopted.

LAND USE AND THE CYPRUS PROBLEM

The Evolution of the Rural Land Use Pattern in Cyprus

By Dr. Demetrious Christodoulou. With Land Use Map, 1 : 253,440, prepared by R. R. Rawson and Dr. K. R. Sealy. (The World Land Use Survey—Regional Monograph No. 2.) Pp. vi+230. (Bude, Cornwall: Geographical Publications, Ltd.; London: Ed. Stanford, Ltd., 1959.) 25s.

FOLLOWING the success of Dr. Tregear's monograph on "Land Use in Hong Kong" (1958), the World Land Use Survey, under Prof. Dudley Stamp's direction, has produced a valuable, and topical, explanatory account of the land use problem in Cyprus. This publication contains what are, in effect, two separate though complementary studies married together by careful editing.

One of these studies, the "Land Utilisation Map of Cyprus", on a scale of approximately 1 : 250,000, was first published in 1956, but it is a great convenience to have it for reference alongside Dr. Christodoulou's monograph. The map itself was prepared from some 10,000 air photographs by a team of workers at the London School of Economics directed by Mr. R. R. Rawson and Dr. K. R. Sealy and records nine categories of use.

Dr. Christodoulou's study reflects, in its form of publication, the earlier publications of the Land Utilization of Britain; in its methods, the author's geographical training in Britain at Southampton and at the London School of Economics; and in the quality and spirit of the writing, his own long experience in the country of his birth, of which he is now land consolidation officer. More recently he has become chairman of a Food and Agriculture Organization working party on the problems of administration of public and common grazing lands in southern Europe, and readers of his study of Cyprus will await his report with more than usual interest.

Though the third largest island in the Mediterranean, Cyprus is no bigger than two English counties, such as Norfolk and Suffolk. The land, and its water supplies, remain the main natural resources, largely supporting a population of 550,000, now increasing at a rate of 1·5 per cent per annum. Marked regional contrasts exist in the degree to which population presses upon land, but overall the mounting population pressure, coupled with an increasing expectation of improved standards of living, are vital factors in the island's social, economic and political life. On the whole, society remains close to the land: about half the adult population is engaged primarily in farming.

The land-use pattern is a varied and complex one. Cyprus presents an unusual variety of cultivations and crops, with rapid variations occurring within a small compass. The complex situation is analysed carefully by a systematic treatment of the principal crop and land-use distributions, by a discussion of the main farming types and through a synthetic examination, region by region, of land use characteristics.

Dr. Christodoulou's assessment of the physical conditions affecting crop production, based upon a nine-fold regional division of land-forms, is straightforward and generally clear. Climate is given special attention in view of the importance of water to the life of this thirsty island. The fundamental significance of winter rainfall, and the adjustment to it of the life-cycle of vegetation and the pattern of human endeavour, are forcefully driven home. The sad record of recurring droughts arising from rainfall variability is long, and a critical treatment is given of schemes to conserve and utilize "the most precious resource" of the island.

But the diverse pattern of village and farm bears also the ineradicable marks of centuries of human labour. Christodoulou shows that, in the final analysis, it is the human or institutional problems, rather than the physical conditions, that provide the most stubborn problems of land use. His chapters on these problems form the most interesting and original parts of the book, for in them Dr. Christodoulou's own personal feeling for the land and its people is most clearly revealed.

The gap between available scientific knowledge and the archaic practices of the mass of peasant farmers is seen to be at the core of the problem: technical education has scarcely begun to narrow the gap while, so long as agriculture remains the least remunerative occupation, there is little prospect of its attracting technically efficient and receptive farmers. Farming problems of to-day bear the burden of a complicated situation of land tenure, the antecedents of which are, in summary, unravelled. Christodoulou feels that much of "the malaise of the rural areas and a serious obstacle to modern agricultural techniques stem from the size and fragmentation of peasant holdings". Holdings are fragmented, plots dispersed and the pattern of ownership diffuse. The financial misfortunes of the Cyprus peasant are not overlooked, and, even if times are better than they were, capital is scarce, returns small and rural indebtedness is a continuing source of rural debilitation. Unfortunately, the section on the internal market is short, necessarily so in the absence of detailed studies, and the impact of town growth on the countryside, though many times suggested, is not separately considered. But there is an excellent account of the evolution and characteristics of the farm and of the main types of farm dwelling.

Dr. Christodoulou's work is critical and firmly based both on field work and on relevant British, Greek and Turkish sources. He is understandably cautious about the future. While not neglecting the many valuable contributions already made, he clearly feels that reorganization of the whole agrarian pattern is essential and that careful planning, based on a full appraisal of the human and natural resources of the island, is overdue.

Problems of land use are fundamental to the social, economic and political issues that beset this troubled island. It is a sad commentary that it is only in the closing days of British administration that such a study, and this from a private source, should become available. Christodoulou's work should quicken attention not only to these issues in Cyprus but also to the study of the use of land in other territories for which responsibility still lies in Britain.

M. J. WISE

SUBMARINE GEOLOGY

The Earth beneath the Sea

By Prof. Francis P. Shepard. Pp. xii+275. (Baltimore, Md.: The Johns Hopkins Press, 1959.) 5 dollars.

PROF. SHEPARD has made a lifelong study of submarine geology, but it is a rapidly advancing subject and he says he has obtained most of his education since he received his doctor's degree. He published his last book on submarine geology twelve years ago. It did not mention turbidity currents and now most students are convinced that they really do charge down continental slopes at the speed of express trains and carry silt hundreds of miles across the ocean floor. The book has much else that is new, largely in physical and geophysical treatment but also in topography. It is written for readers with little technical background though an elementary knowledge of geology or physical geography would be a help.

The author shows how every bit of the ocean floor from the shore lines to the greatest depth is likely to be influenced by currents, tides or some kind of oscillation, and deals successively with the beaches, continental shelves, slopes and the deep ocean floor. He maintains that the action of a lowered sea-level during glacial times was mainly responsible for the shelves, and that the canyons were cut at such times, or during periods of coastal elevation, and worked nowadays by turbidity currents. He is rather sceptical whether the trench of the mid-Atlantic ridge is as long and continuous a feature as recently claimed. In explaining flat-topped seamounts he favours the subsidence hypothesis, and that coral reefs occur where favourable growth conditions allowed the coral to keep pace with subsidence. He deals briefly with investigations using acoustic, seismic, gravity and heat-flow techniques and feels that the work is in too early a stage to allow much more than speculation about events below the ocean bottom.

When dealing with ripple marks, grading of sediments and other characteristics that have been used to date the past, he shows how many ideas have to be changed now that actual observations of what conditions are like on the sea bed have been made, and notes that we have been too much influenced by arguments that were largely philosophical.

G. E. R. DEACON

MINOR ELEMENTS IN SOILS

The Geochemistry of Rare and Dispersed Chemical Elements in Soils

By A. P. Vinogradov. Second edition, revised and enlarged. Translated from the Russian. Pp. ii+209. (New York: Consultants Bureau, Inc.; London: Chapman and Hall, Ltd., 1959.) 9.50 dollars; 80s. net.

THE behaviour of minor elements during the processes of rock weathering and soil formation is described and illustrated in A. P. Vinogradov's "The Geochemistry of Rare and Dispersed Chemical Elements in Soils", now in its second edition. The author assumes a sound knowledge of geochemistry and pedology, thereby limiting the use of the book to geochemists and soil scientists.

Chapter 3 on "General Geochemical Regularities" gives an outline of the various factors which control the distribution of elements in the zone of weathering. The following are briefly discussed: ionic radii, electromotive series, sorptive properties, ionic potential, pH, oxidation-reduction potentials, etc.

The major part of the book describes the distribution of the elements boron, fluorine, bromine, iodine, arsenic, selenium, lithium, rubidium, cesium, strontium, barium, rare earths, titanium, zirconium, vanadium, chromium, manganese, nickel, cobalt, copper, zinc, cadmium, lead and molybdenum in soil profiles which are developed over the sedimentary rocks of the eastern European plain. The soil types dealt with are tundra, podzol, grey forest, chernozem, chestnut, desert serozem, brown soils, and red earths. Comparisons are frequently made with data from similar profiles described in non-Russian literature.

A few generalizations concerning the element under discussion are made at the beginning of each chapter. These are followed by a description of its content in profiles from the various soil-types. Finally, conclusions of the behaviour of the element within the soil are given. Frequently these conclusions are not supported by the data quoted; for example, in Chapter 6 it is stated "in the majority of cases a tendency toward an increase in the content of fluorine in the subsoil was noted". However, in only two of the nineteen profiles presented (Table 20) is there an increase of fluorine in the subsoil. In the remaining seventeen examples quoted there is a decrease.

The behaviour of the elements tin, tungsten, radium, uranium, thorium, ionium, beryllium, scandium, gallium, indium, thallium, germanium, niobium, tantalum, antimony, bismuth, mercury, rhenium, gold, silver, platinum, tellurium and hafnium is briefly mentioned without introducing new data. A comprehensive bibliography contains 560 references, including many non-Russian papers.

Poor editing in the original Russian edition of the book is reflected in the English translation. Numerous errors appear in both the text and tables. Data have not been uniformly presented in some tables and often the units used are not clearly stated. The text on p. 170 should follow that on p. 167.

Despite the many editing errors, the extensive tables should prove useful sources of information on the normal contents of the minor elements in soils of the zonal types considered. A. H. Debnam

NUCLEAR RESEARCH IN THE U.S.S.R.

Atomic Energy in the Soviet Union

By Arnold Kramish. Pp. x+232. (Stanford, Calif.: Stanford University Press; London: Oxford University Press, 1960.) 27*s*. 6*d*. net.

THIS book by Arnold Kramish performs a most useful task in a thoroughly interesting fashion. The writer traces the published evidence of Soviet activity in the field of nuclear studies since before the War, and indeed he pays rather special attention to the important time of development in the early part of the 1930–40 decade. With some hesitation in the mid-war years only, he is able to establish a consistency and breadth of Soviet effort in the field that is altogether impressive. Many scientists who have neglected until recently the original Soviet publications will find the volume a considerable help in tracing some of the important landmarks in Soviet achievement in this field during the past thirty years.

During this time, as the author demonstrates, there have been many vagaries in the policy of the Soviet Union regarding the extent to which publicity has been given to particular advances. The book removes much of this difficulty, and the picture that emerges is one of almost uninterrupted pressure on the large number of well-trained scientists and engineers to make full use of the generous provision of support in both money and materials. As the author points out, our picture is still far from complete because of the secrecy that still surrounds many of the ventures. He points to interesting differences in approach to certain topics for example to the subject of controlled thermonuclear research. It appears to be the policy to be frank in those areas where really fundamental difficulties are present and so to encourage help to come from any possible source. It is no doubt rewarding to ponder on some of these basic differences in approach.

If one has to make any general conclusion from the study it is probably that achievement by scientists and engineers in the Soviet Union, the United States, and Great Britain is more or less proportional to the support afforded and relatively independent of the political background, provided that original thinking or inventiveness is encouraged.

The style of the author is lively and fresh, and the book is very easily digested by those with some background knowledge of modern physics and atomic energy. Its value to scientists, engineers and administrators is obvious, and it can be highly commended. The price is relatively modest at 27*s*. 6*d*., and the volume does not suffer from the absence of illustrations. S. C. Curran

PHYSIOLOGY OF MARINE ANIMALS

The Biology of Marine Animals

By J. A. Colin Nicol. Pp. xi + 707. (London: Sir Isaac Pitman and Sons, Ltd., 1960.) 95*s*. net.

TO those, of whom I am one, who for the past generation and more have worked in the field of comparative physiology of marine animals, this book comes as a revelation of the extent of achievement during this period. Very few of the 1,700 odd references to literature which are among the many virtues of this volume deal with papers earlier than the mid-twenties. It was in that earlier post-war period that the attention of marine biologists began to turn from description, of structure or of life-history, to analysis of function and to the elucidation of physiological as well as of morphological adaptation. Increased knowledge of marine environments went hand in hand with greater understanding of the internal fluid medium in animals and of how problems of osmo-regulation had been solved. Interest extended from the properties of vertebrate hæmoglobin to those of hæmocyanin and of other invertebrate respiratory pigments, as well as to the wider general problems of animal pigments so wonderfully displayed in many marine animals. Then also knowledge of the complexities of the mechanisms of sensation and response began to include analysis of the sense organs and behaviour of marine invertebrates and fishes as well as of the nature of nervous and hormonal control particularly in fishes, cephalopods and crustaceans.

In this impressive volume of 700 pages, Dr. Nicol summarizes the results of these investigations, to which he has himself made very significant contributions. It is a major work of synthesis; it may well be the last time that anyone will attempt single-handed to cover so wide a field, in any event with that meticulous reference to the sources of knowledge here provided. It does not seem that this book could have been done better. It has been, one knew, years in preparation by an author living in the very atmosphere of marine biological research. It would appear, judging from the date of the introduction, to have been four years in process of publication. So, like all such books, it is a little out of date, a matter, however, that will only be apparent to active research workers and then only within their speciality.

Exception might be taken to the title, but then few people would agree about what precisely is meant by biology. Here it covers physiology, extending from body fluids to luminescence (on which the author writes with particular authority), but with final chapters on "Associations: Commensalism, Parasitism and Symbiosis" and "Skeletons, Shelters and Special Defences". There is no mention—and could not be without extension into a second volume—of reproduction, which one feels should be covered in any book dealing with biology. Dr. Nicol might have been better advised to restrict himself to his purely physiological chapters—with suitable change in title—because the final two chapters covering much wider, less-analysed fields are inevitably more condensed and less critical.

These, however, are very minor criticisms of a book that brings many into Dr. Nicol's debt. It is extremely well produced, containing some 300 figures as well chosen as they are reproduced. The publishers may well share some of the congratulations extended to the author but not, surely, when it comes to price. Was it, one may reasonably ask, really necessary to charge almost £5 for a book that should find a place in the library of every university and marine station in the world and be in the possession of everyone scientifically interested in marine animals? C. M. YONGE

A NEW STUDY OF THE BRITISH ODONATA

Dragonflies

By Philip S. Corbet, Cynthia Longfield and N. W. Moore. (The New Naturalist: a Survey of British Natural History.) Pp. xii+260+32 plates. (London: William Collins, Sons and Co., Ltd., 1960.) 42*s*. net.

WITH just over forty species of dragonflies recorded from the British Isles, one might at first question the necessity for another book on these insects, since for the purposes of identification the subject has already been dealt with in two recent publications. The present volume in the "New Naturalist" series is, however, intended more for the naturalist than for the collector and may be considered rather as supplementary to Tillyard's classic, "The Biology of Dragonflies," in which the external and internal morphology of the Odonata was dealt with in great detail, but classification, distribution, fossil history, bionomics, etc., only occupied about one-third of the book. As in other volumes of the "New Naturalist" series, this book is an indication of the changed attitude of the naturalist, with the emphasis on the living insect and its behaviour rather than on dissection and museum study.

Three of its fourteen chapters deal with the composition of the British dragonfly fauna, its history and distribution, and four are devoted to the life-history of the various stages. The behaviour of the adult dragonflies, dispersal and seasonal regulation in dragonflies are the titles of other chapters, and the fossil history of the order and the inter-relationships of dragonflies and other animals (including man) are discussed. Various appendixes include a key to the larvæ of the British dragonflies, a survey of the wing venation and its terminology, methods of preserving colours of dragonflies and of marking dragonflies for behaviour studies.

The three authors are all general naturalists as well as being specialists in different facets of the study of Odonata. Dr. P. S. Corbet made a three-year investigation into various aspects of the life-history of dragonflies the subject of a thesis for his Ph.D. degree. Miss C. Longfield worked for thirty years as an honorary associate in the Department of Entomology, British Museum (Natural History), where she identified and described dragonflies from many parts of the world, including material collected on her own expeditions abroad. Dr. N. W. Moore made his investigations into the ecology and behaviour of adult dragonflies the basis of his Ph.D. degree, and has also studied Odonata in the field in Gambia.

These three authors, each being responsible for different sections of the book, have succeeded in welding their contributions into a homogeneous and very readable whole, without suppressing too much of their individual styles and personalities. Much of the information in the chapters on life-history and behaviour is based on the authors' personal studies, and the occasional use of the first person singular gives life to their accounts and prevents them from appearing too formal to the general reader. The inclusion (as an appendix) of Mr. A. E. Gardner's keys to the larvæ of British dragonflies, with his own illustrations, is a valuable addition to the book. These keys originally appeared in an entomological journal, and their reprinting here will introduce them to a wider public.

The production is entirely up to the standard of the previous volumes, and the work is fully illustrated with plates in both colour and in monochrome and with some line drawings. The line drawings in the chapter on behaviour are an excellent example of how to use bold, simple drawings. There are many colour plates, most of them reproduced from very fine transparencies specially taken by Mr. S. Beaufoy. These were mostly taken under controlled artificial light conditions and are in a sense studio portraits of the living insects. By this means a more uniform colour balance has been obtained, and the background can be chosen to suit the subject. All these colour plates are reproduced at natural size, and while this is an advantage for comparison, it does mean that the smaller specimens lose a certain amount of detail in reproduction. This is particularly noticeable where, as in one or two illustrations in the review copy, one of the colour impressions is slightly out of register. One realizes that to have reproduced the smaller species on a larger scale would have entailed more colour plates and an increase in cost.

As a whole, this is a most interesting book and one which should prove extremely useful not only to students of dragonflies but also to field naturalists and to students, as it not only gives a recent picture of the state of our knowledge of the British Odonata but also shows in what directions further research is needed. D. E. KIMMINS

GROWTH AND FORM IN AN INSECT

The Control of Growth and Form

A Study of the Epidermal Cell in an Insect. By Prof. V. B. Wigglesworth. Pp. vi+140. (Ithaca, New York: Cornell University Press; London: Oxford University Press, 1959.) 21*s*. net.

THIS well-illustrated small book, based on six Messenger Lectures which Prof. V. B. Wigglesworth delivered to a general audience at Cornell University in 1958, displays the epidermal cell of an insect as a medium convenient for the study of the principles of the control of growth and form. The author points out that this limitation of the field of study has both advantages and disadvantages, but the fact that the insect selected is *Rhodnius prolixus*, of which Prof. Wigglesworth has such deep and extensive knowledge, does much to outweigh the disadvantages.

Taking the view that there is much to be said for starting with specialized parts of a complex animal, rather than with a "simple" animal, Prof. Wigglesworth gives a brief description of the complex activities of the epidermal cells in producing the cuticle and later hardening it. He goes on to consider the special cells which become differentiated from the epidermis in the larva of *Rhodnius* and give rise either to dermal glands or sensilla, and puts forward the attractive hypothesis that the fate of the special cells is determined by the concentration of some essential chemical constituent in the epidermis. An epidermal cell which receives an appropriate amount of the essential factor develops into a sensillum, and one receiving a smaller amount into a dermal gland. The active cell first acquiring an effective concentration of the essential factor becomes dominant and by withdrawing the essential factor from its neighbourhood inhibits the development of other sensilla around it. Dermal glands may appear, however, suggesting that they need a lower concentration of the essential factor for their development, a view supported by their closer spacing.

Emphasizing that it is the capacity of the epidermal cells to produce cuticles of different types at different stages of the life-cycle which forms the basis of metamorphosis, Prof. Wigglesworth then discusses the hormones which initiate cuticle development and control its form. The epidermal cell possesses dual potentialities, and produces larval or adult cuticle according to its hormonal environment. It is stimulated to produce cuticle by the growth hormone, which is envisaged as controlling the synthesizing power of the cell by regulating permeability or transport. The juvenile hormone inhibits differentiation towards the adult by accelerating the production of the cuticle, and, since growth ceases when cuticle secretion begins, so limiting the period during which the epidermis can grow and produce a changed body form. Only in the absence of the juvenile hormone can the epidermal cell realize its latent potentiality of laying down cuticle of adult form. Metamorphosis and polymorphism are then discussed in terms of hormonal balance.

The final chapter deals with the integration of growth. The idea that tissue and body fluids convey chemical information on the activity of cells and tissues, so that the activity of one cell is reflected in an environmental change which regulates the activity of another cell, leads to the suggestion that the means of integration are present in generalized form in the epidermal cell and are not restricted to the specialized tissues involved in nervous conduction and hormone secretion.

The labours of many authors over the past twenty years and more have given us much information on the cuticle of insects, and caused us to have, like Prof. Wigglesworth, a profound respect for the epidermal cell which produces such a complex structure. It is refreshing now to have the cell itself considered against the wider background of the control of growth and form. Not only insect physiologists but also biologists generally will be grateful to Prof. Wigglesworth for this book. R. DENNELL

INTERNATIONAL CYTOLOGY

International Review of Cytology

Vol. 8. Edited by G. H. Bourne and J. F. Danielli. Pp. x+541. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1959.) 13 dollars.

THIS volume contains the useful address given to a plenary session of the International Congress for Cell Biology in September, 1957, by the veteran French cytologist, Charles Oberling, who has recently died. Besides Oberling on the structure of the cytoplasm, there are fourteen other contributors. Teachers of general zoology will be interested in the papers by Milton Fingerman (physiology of chromatophores) and C. F. Ehret and E. L. Powers (cell surface of *Paramecium*). Cell physiologists will note the work of D. B. Roodyn (metabolic studies on isolated nuclei), D. A. T. Dick (osmotic properties of living cells), H. Holter (pinocytosis) and I. M. Glynn (sodium and potassium movements in nerve muscle and red cells). Histologists will be helped by reading the papers by Leah Lowenstein (mammalian reticulocyte), David Hall (fibrous components of connective tissue, with special reference to elastic fibre), J. B. Bridges (experimental heterotopic ossification) and E. de Robertis (submicroscopic morphology of the synapse). In addition R. D. Preston has considered the wall organization in plant cells, and Bert Vallee and Frederic Hoch have a paper on trace elements in cellular function. The various authors come from France, the United States, Denmark, Argentina, Great Britain and Ireland. It is, of course, an honour to have a paper accepted for this splendid series, and the present contributions are correspondingly valuable.

Some of the papers, such as those of Roodyn, Dick and Glynn, are very complicated and hard going. Where possible the authors have discussed the electron microscopy of their field. The work of Ehret and Powers, which recalls that of Sedar, Porter, Manton and Roth, reminds us that morphological protistology is being re-written by electron microscopists. In his essay, Oberling touched on the past and looked to the future. He mentioned the dismissal in past times as artefacts of all granular, reticular and spongy structures in the cytoplasm, which had led to so much controversy. He wrote: "My generation has lived through this period, and those who in spite of their disappointments have remained morphologists, suffered a good deal". He attributes the past confusion to the physicochemists. This is only partly true. Up to very recent times the cytologists themselves provided most of the ground for controversy. In 1927–28 Covell and Scott stated that the Golgi apparatus of neurones was formed of neutral red-staining droplets, a view supported by E. V. Cowdry in his widely used "Text Book of Histology" (1938); and in 1949, Palade and Claude considered that the Golgi apparatus was formed of myelin droplets, which were supposed to be something different from the germ cell dictyosome (Golgi body). These papers emanated from the Rockefeller Laboratory, and the basic views they advocated were unsound. It is scarcely necessary in Britain to recall the confusion of views at the Royal Microscopical Society's symposium on the Golgi apparatus in 1955.

The position to-day is that, leaving aside ergastoplasm (and plastids), there are three recognized and separate 'large' extra-nuclear cell inclusions—Golgi apparatus, mitochondria and centriole. The latter is a short tube with nine spaced fibrils embedded in its wall. The mitochondria consist of a matrix surrounded by a double membrane, the inner infolded at intervals. The reasons for, and function of, these two membranes are unknown. The mitochondria can divide by binary or multiple fission (*en rosace*). The Golgi apparatus, which also can divide and grow, consists of a dictyosome or aggregated group of dictyosomes formed of layers of oval or rectangular collapsed saccules or membranes, piled up usually closely to form a polarized lozenge-shaped body, in the hollowed base of which a secretion globule may appear. Watery vacuoles, either peripheral or basal or both, almost always become associated with the membranes, and chains of such covered vacuoles constitute the canals of Cajal of neurones. So universal is the dictyosome in its similarity that only a specialist could express an opinion as to whether a given electron micrograph of a Golgi body belonged to *Nemobius*, *Homo*, *Chromulina* or *Elodea*. Here is a universal cell device (or apparatus), vaguely considered as a filter or secretory body, the manner of functioning of which also is unknown. The understanding of this universally similar morphology of the Golgi apparatus is one of the two great basic discoveries due to electron microscopy. The other basic discovery is the understanding of the universality of the 9 + 1 fibrils in cilia and flagella, a truly astonishing thing.

As to the future, Charles Oberling wrote: "Each degree of magnification needs its mode of preservation (of the cells), and I am afraid that it is this prerequisite and not the magnifying power of electron or proton microscopy which will prevent us for the time being, from filling the gap between morphology and chemistry. But let us enjoy the tremendous opportunities within our reach of rich harvests and exciting discoveries for generations of workers".

J. BRONTË GATENBY

MEDICINE AS A SOCIAL SCIENCE

Mirage of Health

Utopias, Progress and Biological Change. By Dr. René Dubos. (World Perspectives, Vol. 18.) Pp. 231. (London: George Allen and Unwin, Ltd., 1960.) 21*s.* net.

THE increasing use of insecticides with their striking and sometimes frightening effects, our recent experience of myxomatosis as well as other odd changes in some bird and animal populations, have made most of us aware of the importance of 'animal' ecology. However, the notion of a 'human' ecology —a study of the balance between environment and human populations—is much less widespread. But the subject is certainly no less complex, and it may be a good deal more exciting if only because the so-called natural balance of things has for ages been knocked about by the whims and fancies of man. His growing ability to control his own destiny and the implications of this control are the broad subject of this book.

One of the whims and fancies which man has cherished down the ages in all societies is that perfect health and happiness are just around the corner. But a life free from pathogens, like the two-car Utopia for which we strive, has its snags, and is probably undesirable as well as impractical. It seems scarcely necessary to say that we know very little about even our major diseases. For example, all infections do not mean clinical illness; some of us with severely damaged arteries do not die of coronary occlusion, and disorganized and cancerous cells have an inexplicable way of disappearing from some patients. Illustrations such as these merely serve to underline the complexity of the interrelated causes of disease—the ecological system in which we live. They provide additional reasons, if any were needed, for throwing overboard the cosy doctrine of specific ætiology and prompt us yet again to reflect upon the wider repercussions of our attack upon disease.

That we live within these finely balanced systems has been recognized for many years and by many writers—its importance for cognitive psychology was emphasized by the *Gestalt* theorists of the 'thirties and for social medicine by Ryle and others in the late 'forties. René Dubos in 1960 has brought together a mass of historical, sociological and biological facts which constitute a fascinating and popular account of this human ecology, an account which is both exciting and provocative.

The World Perspective Series seeks "to reveal basic new trends in modern civilization, . . . and to point to the new consciousness which can contribute to a deeper understanding of the interrelation of man and the universe, the individual and society, and of the values shared by all people". These are high hopes and must be difficult of attainment. Dr. Dubos does not attempt anything so spectacular, but in a quiet way he reaches at least one of these ill-phrased objectives. He traces first the notions of an earthly paradise—of health and happiness—through historical times to the present day and shows how we have developed a touching and altogether unwarranted faith in laboratory science alone. That man can become completely healthy by the simple process of spending money on research is believed by most Americans and many Europeans. 'Health is purchasable' say the doctors, and the National Institutes of Health are embarrassed by the amount of research money which they control. Dr. Dubos emphasizes the contrast between these simple half-truths and the reluctance of Western people to alter ways of life along the lines advocated by the very research workers whose studies they have sponsored. As a result, the patterns change and there is less typhoid and cholera, but at the same time mental disease and heart disease, to say nothing of motor-vehicle accidents, are already taking their places as the epidemics of the future.

After describing biological and social adaptation in various species and communities, the author is in a position to guess at some of the 'risks' which might attend perfect health. Among these risks he sees a decline in our ability to resist biological stress. In short, he feels that were man ever to achieve 'healthiness', he might well be like so many laboratory animals, in danger of the etiolation which comes from an unchallenged existence.

The three related themes of danger—from the decline in the importance of biological selection, from the rising power of man to control his own destiny, and from the changing patterns of disease—thread fascinatingly through the rest of the book. The Plague, Darwin, Pasteur, Dr. Snow and cholera, the Irish famine, the concentration camps in Germany and the contributions of Greek medicine, are all used to build a picture of man's health in relation to his changing social and biological environment. Dr. Dubos ends with a summary word of caution: the creation of a self-chosen pattern of life remains a gamble; Nature will strike back. "It is," as he says, "always risky to tamper with the natural balance of forces in nature."

One might reply: "Of course it is, but that is how we learn". But Dr. Dubos' book is much more than a plea for caution in our dangerously slap-dash thinking about health. It is a learned, well-written and delightful introduction to medicine as a social science. It must be read particularly by the new generation of doctors, the human biologists as yet unencumbered by the pile of facts and loose thinking that is curative medicine to-day.

E. MAURICE BACKETT

SOME ASPECTS OF ATHEROSCLEROSIS

Hormones and Atherosclerosis

Proceedings of the Conference held in Brighton, Utah, March 11–14, 1958. Edited by Gregory Pincus. Pp. xvi+484. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1959.) 13.50 dollars.

Connective Tissue, Thrombosis, and Atherosclerosis

Proceedings of a Conference held at Princeton, N.J., May 12–14, 1958. Edited by Irvine H. Page. Pp. x+316. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1959.) 9.50 dollars.

THE proceedings of these Conferences are complementary to one another and contain a very worthwhile cross-section of much experimental work in the field of atherosclerosis.

"Hormones and Atherosclerosis" has a collection of 32 papers devoted to various endocrine influences in cholesterol metabolism in experimental animals and in humans. The book opens with short but excellent articles on the biosynthesis of cholesterol by Bloch and Popjak and these are followed by an authoritative account of cholesterol degradation to bile acids by Bergström. The subsequent essays are mainly devoted to the influences of various hormones on lipid metabolism in different species. In the early part of the book the emphasis is on the effects of the thyroid hormones on cholesterol biosynthesis, turnover and concentration in different tissues, by Gould, Milch, Boyd, Pick and others. A considerable part of the monograph is devoted to further experiments on the well-known effects of œstrogens on lipid metabolism, including a discussion on the prediction of œstrogenic side-effects of steroids in man by Drill and co-workers, and a series of essays on the possible usefulness of œstrogens as cholesterol depressants in man by Oliver, Katz, Robinson and Marmorston. The influences of the adrenal cortex and stress are dealt with by Friedman, Seifter, Rosenman, Adlersberg and Furman.

"Connective Tissue, Thrombosis, and Atherosclerosis" contains 16 articles covering a fairly wide spectrum of the field. Duguid presents a clear account of his concepts of atherogenesis and the role of connective tissues in arterial disease, while the chemistry of connective tissue receives a brief but stimulating treatment by Jackson.

The role of elastic tissue in atherosclerosis is briefly dealt with by Lansing, while an outline of the chemistry of the ground substance is treated by Meyer and his colleagues. Some of the metabolic activities of fibroblasts as studied by the implanted sponge method are reviewed by Noble and her associates.

Blood coagulation, fibrinolysis and the countless ramifications of this complex field are treated by Ratnoff, Astrup, Sherry, von Kaulla and their associates. The symposium also contains valuable contributions on the macromolecular basis of collagen structure by Schmidt and Glimcher.

Taken collectively these two books provide a very useful addition to the modern literature on atherosclerosis. On one hand the former emphasizes the many factors which influence lipid metabolism and will be welcomed by all who work on the metabolic aspects of atherosclerosis. The latter review, with its emphasis on the thrombotic facet of atherosclerosis, will tend to restore the balance which is all too frequently absent in many monographs or colloquia on atherosclerosis.

The books are well written, clearly illustrated and very readable, and will prove useful to all interested in the general aspects of atherosclerosis.

G. S. BOYD

A PHILOSOPHY OF COSMOLOGY

Towards a Unified Cosmology

By Prof. Reginald O. Kapp. Pp. 303. (London: Hutchinson and Co. (Publishers), Ltd., 1960.) 35s. net.

COSMOLOGY is a difficult subject, not only because of the nature of its subject-matter but also because the methods of approach are of a kind with which we are quite unfamiliar in other branches of science, but even among works on cosmology the present book is a difficult one to review.

The main difficulty is the author's insistence on the "Principle of Minimum Assumption". His hypothesis, which is really a hypothesis in the philosophy of science but which he considers to be also a truly scientific hypothesis because he can confirm it in a number of cases, is that in physics the minimum assumption always constitutes the true generalization. As an example, by the minimum assumption for the number of planets in the solar system is meant the unspecific assumption that any number of planets can occur. Now, it is quite possible to call this the minimum assumption if the author so wishes, but this procedure of making the minimum assumption is diametrically opposed to the method actually employed in science, and to the method which many philosophers of science think should be employed, for the minimum assumption is the very hardest one to refute. But many of us believe that the best assumption is the one which lays itself open most readily to possible refutation. However, by means of this hypothesis of the minimum assumption, the author was led to the conclusion that a satisfactory cosmological theory requires a continual creation and annihilation of matter, and he was led to this before the Cambridge cosmologists postulated the continual creation which leads to the steady-state theory. It is puzzling that his assumption should lead to a conclusion which is not so very different from the one to which the Cambridge cosmologists were led by exactly the opposite view, that is, by looking for the most refutable assumption.

The author does not deal very fully with the difficulty that annihilation of matter may well lead to experimental effects which have not been observed; for example, to the half-life of the proton which one would expect to be able to measure. But I do not wish to be altogether critical of the book. There are many interesting flashes of insight scattered about it, notably a discussion about gravitation. The author lists a set of problems about gravitation; for example, Why should there exist a field which tends to increase its sources, unlike every other field, which tends to decrease them (because like masses attract)? Why, indeed, do like masses attract, and why have we only ever found positive gravitational masses? Why does the inertial mass always occur in association with an active gravitational mass (if, as I would accept, the general theory of relativity merely incorporates the equivalence of inertial and passive gravitational masses)? Why is there only a limited number of constant ratios between unit charge and the inertial mass of the elementary particles? Can one reconcile what is known about gravitation with action at a distance? All these seem to me questions which are worth asking at this particular time.

ESSAYS IN COMPARATIVE EDUCATION

The Child, the Parent and the State

By James Bryant Conant. Pp. vi+211. (Cambridge, Mass.: Harvard University Press; London: Oxford University Press, 1959.) 28s. net.

SPUTNIK I had a traumatic effect on public opinion in the United States. A scapegoat seemed necessary, and the public education system was selected. Education and educationists—already under fire from several quarters—were increasingly blamed for the apparent failure of the United States to meet the Soviet challenge. Some of the criticism has been virulent, polemical and not infrequently uninformed. Fortunately Dr. James Bryant Conant, the very distinguished scientist, educational administrator, statesman and diplomat, has entered the fray.

Conant's tremendous contribution to the debate in the collection of essays under review is that his criticism of American education is, as befits a scientist, cautious, balanced and thoroughly informed. He chides its more violent critics, but nevertheless examines the problems of American education within the framework of the Soviet challenge to his country. He is not inclined to see it solely, or even principally, in terms of scientific and technological man-power although this aspect cannot be denied. Rather does he accept Comte's view that the great task of education is to rear "a generation of citizens who will be able to rise to the moral and intellectual challenge of these fateful times". In these terms, Conant appreciates that too few American educators have recognized the international post-war role of their country and that too many still continue to believe that "they can live and prosper in an isolated, insulated United States". He sees the larger problems as those of preparing "men and women who can exercise wise leadership" and of developing "intelligent discrimination in future voters". These are formidable tasks indeed, but tasks which Conant admits have been conscious objectives in American education for a long time.

In the face of these problems the process of policy formulation in the United States is one of great complexity. Fundamentally, as the author's title suggests, there is conflict between the interests and demands of children and parents and those of the State. Hence much of Conant's analysis deals comparatively with the mechanics of policy-making in the United States and in Europe. The crucial issue concerns the part the State should play in the maintenance of academic standards, the organization of the curriculum, the training and qualification of teachers, and the finance of schools. Some of Conant's suggestions sound somewhat platitudinous, but one at least is bold. If taken seriously his plea for Federal aid on a large scale for education is bound to provoke controversy. His own proposals regarding the consolidation of 'high schools', the teaching of foreign languages and the place of mathematics and science in the curriculum are moderate and likely to appeal to the practical educator. His support of vocational schools and for some kind of day continuation system is more novel. Many serious educators, however, will think of his proposals as little more than temporary expedients.

Unlike many critics Conant is aware of the difficulties of reforming education. He recognizes, for example, that some policy decisions are not reversible and makes clear that changing conditions in the United States had more to do with the changes in the educational system than irresponsible theorists. In the face of several possible policies from which to choose Conant consistently applies the pragmatic test of asking what consequences—social, political, economic and educational—are likely to flow from the adoption of any one of them. Indeed, one might hazard the guess that he regards the task of prediction as central to the serious study of education. Certainly only through improvements in this field can the study of education grow into a science.

Conant's own method of inquiry—stated by him to be empirical—seems basically pragmatic. His insights are revealing, his analysis of problems acute, and some of his solutions bold. Yet some doubts might be raised about the effectiveness of his comparative approach. The text and very full notes contain much information about the schools of Europe. The appendixes provide a valuable digest of Mr. Khrushchev's memorandum on Soviet education of September 21, 1958, and an extract from the December, 1958, "Law of the Supreme Soviet on School Reorganization". Parenthetically, both documents reveal how universal are some of the problems of education in this technological age. But his analysis of policy formulation in mid-nineteenth century England, present-day Western Germany and the Soviet Union seems dangerously to over-simplify very complex and subtle processes. There are, in brief, rather more sophisticated models on which to base comparative education studies.

Finally, in distrusting discussions about the meaning—and presumably the aims—of education and in eschewing theory in favour of an empirical approach, Conant seems to have failed to distinguish between normative theories and predictive theories. Students of education, in fact, are in real need of the latter and it might be that comparative studies, more than any other type, might make a significant contribution to this task.

Brian Holmes

The Making of the Broads

A Reconstruction of their Origin in the Light of New Evidence. By Dr. J. M. Lambert, J. N. Jennings, C. T. Smith, Charles Green and J. N. Hutchinson. (R.G.S. Research Series, No. 3.) Pp. vii+153+7 plates. (London: Royal Geographical Society, and John Murray (Publishers), Ltd., 1960.) 25s.

THOUSANDS of people know the "Broads". What pleasant memories they evoke—lovely country, interesting bird life, good sailing, joyous parties aboard a motor launch! But how many holiday makers have ever asked themselves how these large lakes were formed? Clearly they are different from any other sheets of water in Britain; How did they come into being? Much research has been devoted to this problem of recent years, and it has been attacked from various points of view—geological, historical, philological, botanical, etc. As the outcome of these investigations it would seem that everything now points to the conclusion that the broads resulted from peat diggings during the Middle Ages. Somewhere about the fourteenth century slight land sinkage, perhaps combined with a tidal break-through such as occurred a few years ago, flooded the peat workings, and this flood water could not drain away owing to the new lower level of the land relative to the sea. The broads, then, were turbaries. It can be shown that, as should be the case, they have vertical peat sides, nowadays somewhat masked by subsequent slight infilling of silt and mud, and we can sometimes also notice transverse baulks of undug peat forming ridges, to-day only just covered by the water; there are also islands of peat similarly only just below water-level. Historical records show that vast peat workings did exist in this area in the early Middle Ages, and the method of working can be determined. Fairly suddenly these methods changed, and much of the peat exploitation ceased. This would seem to correspond with the flooding of the workings.

It must be remembered that transport in the eleventh, twelfth and thirteenth centuries was difficult, and little suitable fuel other than peat existed in East Anglia, which nevertheless was a well-populated part of the country. That peat digging should have existed on a large scale is not surprising. The fact of land sinkage perhaps coupled with tidal break-throughs altered the whole picture and resulted in the broads we know to-day. So whether the holiday maker is sailing over aristocratic Ranworth or stately Barton or proletarian Wroxham, let him spare a moment to remember the old peat workers, his forerunners, to whose labours his present enjoyment is due.

MILES BURKITT

Premier Colloque International de Photographie Corpusculaire, Strasbourg, 1er au 6 Juillet, 1957

(Colloques Internationaux du Centre National de la Recherche Scientifique, No. 79.) Pp. 451. (Paris: Centre National de la Recherche Scientifique, 1958.) 5,300 francs.

THE introduction of the photographic emulsion as a detector of charged particles has had an impact on physics which will be familiar to students of evolutionary biology. We can recognize a long and rather obscure development period, a sudden emergence as a practical device, and then an explosive deployment into many fields and applications as its very adaptable features were recognized. In about a decade a vast literature has grown around the subject of nuclear track plates which must bewilder those about to use them for the first time. Nor are there any signs that track plates have reached the final stage of the evolutionary process, namely, the slow decline and ultimate extinction in the face of the competition from newer types of charged particle detectors. This is evident from the subjects covered in this book, which is a record of the First International Conference on Particle Track Photography held at Strasbourg in 1957. The main aims of this conference were to examine the present state of our knowledge concerning the photographic action of charged particles, to survey the results obtained in recent years, and to seek ways of improving the emulsions to meet the changing requirements of physics and the widening fields of application. There are about fifty contributions by delegates from fourteen countries on the theory of latent image formation, the preparation, properties, processing and application of nuclear emulsions. The book is well illustrated by diagrams and photographs and provides a valuable account of the latest techniques written by experts, many of whom were pioneers in the development of track-plate photography.

D. L. ALLAN

The Transits of Venus

A Study of Eighteenth-Century Science. By Prof. Harry Woolf. Pp. xiii+258+11 plates. (Princeton, N.J.: Princeton University Press; London: Oxford University Press, 1959.) 48s. net.

IF one says of this book that it is a careful and scholarly work describing the aims and adventures of those who, in the eighteenth century, tried to determine the distance of the Earth from the Sun by observations of Venus on the rare occasions when the planet was seen projected on the solar disk, one has said almost everything possible by way of general appreciation.

As a contribution to the history of astronomy this is an important work which will be useful primarily as a complete record of the hopes and fears, successes and failures, hair-breadth escapes and solid achievement of the many scientists and travellers who took part in the observational schemes. One can, however, see more in the volume than a catalogue of historical sources. The tale, considered as a whole, shows how essentially modern the eighteenth century was, and how particularly France, Britain and Sweden could even at that time plan great scientific projects in a manner which would not be out of place to-day. The science of the seventeenth century still had recognizable roots in medievalism: that of the eighteenth looked forward with a philosophy still unchanged in our own time. It is even conceivable that we could draw a modern lesson from this record, and by the use of multiple photography of Mercury or Venus when projected on the solar disk overcome the uncertainties introduced by the indefiniteness of the solar limb in any one exposure, and reintroduce the transit method as a modern means for the determination of the solar parallax.

DAVID S. EVANS

Évacuation et Récupération de la Chaleur des Réacteurs Nucléaires

Par Richard Alami et Paul Ageron. (Introduction au Génie Nucléaire, Tome 3.) Pp. ix+246. (Paris: Dunod, 1958.) 2,900 francs.

THIS, the third volume of an introduction to nuclear energy, is devoted to the removal and utilization of heat from nuclear reactors. The work is directed towards engineering students and those already engaged in the nuclear field who are not specializing in heat transfer.

The first of the four chapters commences with a discussion of the way in which heat is produced in a nuclear reactor. The fundamental laws of heat transfer are next reviewed, and then, after defining the required characteristics of a nuclear coolant, separate sections are given to aqueous, gaseous, liquid-metal and organic coolants. The chapter concludes with a section on aqueous and liquid-metal fuels.

The second chapter deals with the conversion of heat to mechanical energy and includes separate sections on steam and gas turbine cycles. The third covers application of theory to practical reactor systems, some thirteen projects being described according to their coolant classification. The final chapter details methods of determining thermal stresses in simple geometries.

The presentation is attractive, and the text is supported by adequate diagrams and worked examples. Comprehensive tables of physical properties are arranged conveniently within the text. Each chapter includes a reasonable bibliography of supporting references.

The work affords a useful introduction to the subject, but, without implying any criticism of it, it would seem that English readers are already adequately catered for by a number of existing British and American books. R. J. Symes

Nigeria's Feeding-Stuffs

Their Composition and Nutritive Value. By V. A. Oyenuga. Second edition. Pp. 65. (Ibadan, Nigeria: University Press, 1959.) 8*s.* 6*d.*

AGRICULTURAL progress in all under-developed countries has been delayed because of a lack of knowledge, particularly of the basic facts about the soil and the crops of these regions. Overworked staff in Government research stations have usually been overwhelmed by the need to give all their attention to problems of immediate practical importance. Many of us hoped that the new university colleges would do something to encourage fundamental research, particularly in the sciences relating to agriculture. This book shows one instance of this hope being fulfilled. It is particularly encouraging to find that Nigerian members of staff, like Dr. Oyenuga, are making such a useful contribution to the development of scientific agriculture in their own country.

This book, which is a revision and expansion of the first edition published in 1955, lists the majority of the important foods, both of man and his livestock, which grow in Nigeria. It gives analyses of their composition, including such data as their protein and starch equivalent, and their nutritive value. Useful notes on the cultivation and use of each crop are included. Readers who do not know Nigeria may sometimes be surprised, for example, by such statements as that the water melon has the highest calorific value (658 calories per 100 gm.) of any that has been determined; the mystery is cleared up by the explanation that in Nigeria water melons are grown for their seeds and not for their watery flesh. All who work on problems of nutrition on man or animals in tropical countries, and particularly in West Africa, will find Dr. Oyenuga's book a very useful tool. Kenneth Mellanby

Australian Native Plants for Home Gardens

By A. E. Brooks. Pp. xvi+149+40 plates. (Melbourne and Sydney: Lothian Publishing Company, Pty., Ltd., 1959.) 45*s.*

THE Australian bush is particularly rich in beautiful floriferous plants fit to grace any garden. Many have already been brought into cultivation, and the aim of this book is to make known to the increasing number of native plant enthusiasts which species are obtainable from nurserymen in Australia and the treatment they require in the garden. The information is presented in dictionary form with brief descriptive and cultural notes arranged alphabetically under the botanical names. Popular names are given also, and an index is provided for them. Articles on such topics as propagation, manuring and transplanting are interspersed, and, together with lists of species flowering at different seasons, or suited to particular conditions, add much to the usefulness of the book. Very few of the plants mentioned can be cultivated out of doors in the British Isles. For the London area they would include one *Grevillea* and one or two ti-trees (*Leptospermum* spp.) among the shrubs, and the golden everlasting (*Helichrysum bracteatum*) and Swan River daisy (*Brachycome iberidifolia*) among the herbs. The paucity of hardy species combined with the inadequacy of the descriptive matter for identification and absence of keys limits the sphere of usefulness of the book to Australia. These deficiencies are to some extent ameliorated by the inclusion of seventy photographs of a high standard by which the majority of the genera are illustrated. R. Melville

Antibiotic Therapy and Staphylococcal Diseases

Edited by Dr. Henry Welch and Prof. Maxwell Finland. (Antibiotics Monographs, No. 12.) Pp. xii+208. (New York: Medical Encyclopedia, Inc.; London: Interscience Publishers, Ltd., 1959.) 4.50 dollars.

THIS volume is No. 12 in the series of "Antibiotics Monographs" and covers the important subject of antibiotics effective against staphylococcal infections.

After a foreword in characteristic style by Marti-Ibanez, the first chapter by Welch deals with the staphylococcal problem and the effects of early antibiotics, penicillin, chloramphenicol, the tetracyclines and bacitracin. The next six chapters deal with erythromycin, oleandomycin, novobiocin, vancomycin, ristocetin, and kanamycin. Each is written by a well-known authority in the use of these antibiotics. The last chapter consists of recapitulation and discussion by Finland.

The book is excellently produced. It gives much useful information about each of the antibiotics considered, full references to their use in clinical practice, an assessment of their effectiveness and discussion of the ease with which drug-resistant organisms arise.

It ends with the conclusion that antibiotics against staphylococci should be used sensibly and only for clear indications, that they should never be used for prophylaxis on a wide scale in hospitals or in closed communities particularly for long periods, that the antibiotics most suitable for each case should be selected and changes made after adequate trial has shown them to be ineffective or inadequate, or when other infections are demonstrated or evidence of toxicity precludes their further use. R. Knox

ARE THE LAWS OF NATURE SYMMETRICAL?

By PROF. O. R. FRISCH, O.B.E., F.R.S.*

BY symmetry I shall mean mirror symmetry, exhibited by such flat figures as a heart or a fleur-de-lis or the letter A. There are two tests for symmetry. One is to see if a plane can be found—the plane of symmetry—which bisects the figure so that, of the two halves, one is the mirror image of the other. Hence, any figure together with its mirror image in an arbitrary plane constitutes a symmetrical figure. The other test is to form the mirror image of the given figure and see if the two look alike. Children might find it difficult to perform that test since they notoriously confuse *d* and *b*, or *p* and *q* (but would they call them alike if they saw them side by side ?). But apart from that the two tests are equivalent, for flat figures; though not for spatial shapes, as we shall see.

Considered as a shape in space, any flat figure is symmetrical, its own plane being the plane of symmetry. The flat shape of a glove is symmetrical, but not the glove itself, the two sides of which are different. Many crystals are symmetrical, but some are not. Many of them will pass the first test—of having a plane of symmetry—and it is easy to prove that they then also pass the second test, of being 'congruent' with their mirror image. But the converse is not true: there are shapes that are congruent with their mirror images but that have no plane of symmetry. This is, of course, well known to crystallographers, but seems surprising when first encountered. Actually we know much more complex forms of symmetry, with several planes of symmetry; but here I am concerned only with the basic difference between symmetrical and asymmetrical shapes.

The important point is that the internal measurements of any shape are not changed when it is mirrored. Hence, for any asymmetrical shape there exist two forms, say, a right-handed and a left-handed one, and the internal measurements are the same for the two. For example, two helices may be drawn on cylinders of the same size, and at the same pitch, and yet be quite different. One is related to our right hand as the other is to our left hand, and so a convention for naming them has come about; but this can be used only by beings who know what we mean by right and left.

So geometry gives no preference to any shape over its mirror image. Does physics ? To put it more precisely: any set of geometrical measurements, carried out on a given shape, will give the same results if carried out on its image. Is the same still true if we extend it from geometrical measurements—of lengths and angles—to physical measurements, say, of speeds or forces or temperatures ? Would any experimental arrangement give the same result as its mirror image ?

The fundamental laws of Newton on which mechanics is based certainly make no distinction between right and left. A weight hung on a string can be made to swing in a circle, and the time for a turn is the same whether it swings clockwise or anti-clockwise. Actually, there is a slight difference because the Earth is turning; this can be eliminated by doing the experiment on the equator, or by just correcting for it. Even then there may be a difference because the string is twisted; so we should strictly use two weights hung by strings which are twisted the opposite way! Anyhow, if all such trivial errors are avoided, the direction of swing makes no difference.

The passage of polarized light through a sugar solution seems to be different. In the absence of the solution, minimum light is obtained with the two Nicol prisms crossed; but with the solution in the light-path, the second prism must be turned to the left to restore darkness. Here we seem to have an asymmetric phenomenon: with the mirror image of this arrangement, that is, with the prism turned to the right, we get brighter light rather than darkness. But the sugar molecules are the cause of that asymmetry; they are twisted, and if we replace them by others which are their mirror image and then turn the prism to the right, we shall once again get darkness, and symmetry is restored.

In the same way we can explain the apparent asymmetry of Oersted's famous experiment, which greatly worried him and his contemporaries. A compass needle above a horizontal wire and parallel to it is deflected when we pass a current through the wire. As before, an apparently symmetrical arrangement gives an unsymmetrical result. But the arrangement is not really symmetrical. The magnetism of the compass needle should be attributed, according to Ampère, to electric currents that go around it. Hence the arrangement is no longer symmetrical; in order to convert it to its mirror image the needle must be turned round, and then the current, of course, deflects it in the opposite sense, as demanded by symmetry.

I hope these examples will make it plausible that the laws of classical physics are indeed symmetrical. Here I mean by classical those phenomena where macroscopic bodies are concerned, made from very large numbers of atoms. But in this century we have learned to observe single atoms, and here a new difficulty appears. An atom passing through a layer

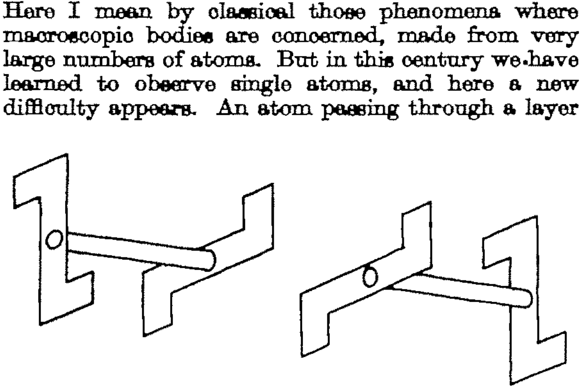

Fig. 1. These two shapes are identical (congruent), as can be seen by turning one by 90° about its rod, and are also mirror images of each other; yet each has no mirror plane

---

* Substance of an Evening Discourse at the Royal Institution, delivered on May 11.

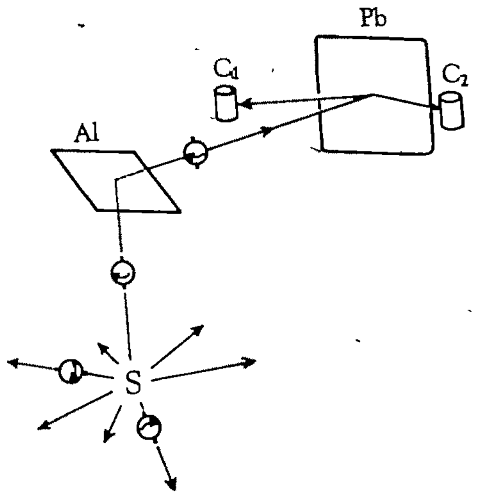

Fig. 2. Electrons from a beta-active source S tend to spin to the left about their direction of flight; that can be shown by scattering them twice, first from an aluminium foil Al and then from a lead foil Pb. The two symmetrically placed counters, C_1 and C_2, then count at slightly different rates

of gas or an electron passing through a metal foil will suffer a random deflexion, either to the right or to the left. Whichever it does, it behaves unsymmetrically in a symmetrical situation. But what else can it do? Its only alternative would be to remain undeflected, like Buridan's ass, which starved between two equal bundles of hay, obedient to the principle of symmetry. A real ass would eat one of the hay bundles at random, and nobody nowadays would worry about its unsymmetrical action. If out of 10,000 asses in that situation 6,000 turned to the right and only 4,000 to the left, then we might deduce that asses behave unsymmetrically; from the action of one ass nothing follows.

So in studying single atoms we must study them many times, or many of them, and analyse the results statistically. Until 1957 (with one single exception) no atomic process had been found to behave unsymmetrically, when averaged over many repetitions. But in 1956 reasons were given to suspect the radioactive beta-decay of unsymmetrical features, and early in 1957 a number of experiments were performed that confirmed this suspicion.

Radioactive phosphorus emits electrons in all directions. If a stream of those electrons that travel vertically upward is made to strike a sheet of aluminium, and those that are thereby deflected by 90° are then made to strike a sheet of lead plate, we should expect that of the electrons that are deflected by the lead plate, equal numbers should go to the right and to the left. But experiment shows that this is not so: about 10 per cent more electrons are recorded on the right than on the left.

Since the arrangement is quite symmetrical, the two positions of the counter represent two experimental arrangements, one the mirror image of the other; yet they give different counting rates. But before I discuss the wider implications of this, I want to describe the mechanism that accounts for this result. It is easy to verify that the electrons reach the lead plate as a symmetrical stream; Why, then, are more of them deflected to the right than to the left? Reversing the lead plate makes no difference, so it must be some property of the electrons. Now, a similar behaviour is seen with a tennis ball that has been given a spin about an axis across its direction of flight: striking a surface normally, it yet tends to go off sideways. The electrons do not, of course, bound back from the lead plate like balls from the floor, but rather like balls from an irregular array of nail heads which represent the atomic nuclei in the lead plate. Even so, the spin does cause an asymmetry in the deflexion pattern, and that asymmetry was indeed calculated by Mott as early as 1929, as soon as Dirac had formulated his mathematical theory of the electron spin.

So the asymmetry we observe indicates that the electrons strike the lead plate with a tendency to spin to the right rather than to the left, like couples performing a Vienna valse. Of course, they were originally travelling upward from the radioactive source before they were deflected by the aluminium sheet. Such a deflexion has little effect on the spin; so we finally conclude that the asymmetry comes from the fact that the radioactive nucleus tends to give each electron a spin to the left on sending it off.

That conclusion could have been reached in 1930: for in that year C. T. Chase found the same asymmetry (see *Phys. Rev.*, 36, 1060; 1930). But the time was not ripe; the effect was small and seemed inexplicable; nobody took notice, and the experiment was soon forgotten. Of course, electrons always spin, but usually in a random manner; and, indeed, when Chase's experiment was repeated with electrons from a hot wire, the asymmetry disappeared (which was erroneously taken to mean that his original experiment had been in error). How then does the nucleus cause the emitted electron to fly off with a definite sense of spin?

To that kind of question physics has no answer, no more than to the question: How does a positive charge attract a negative one? The attraction between opposite charges and many other more complicated electric and magnetic phenomena are fully described by Maxwell's equations; but not 'explained', since that would require their reduction to something more fundamental, and no such reduction has yet been achieved (although Einstein and others have tried). In the same way, the emission of electrons from radioactive nuclei is described in every detail, including the direction of spin, by a theory of which the foundations were laid by Fermi, more than twenty-five years ago.

In its original form, Fermi's theory did not predict any preferential direction of the electron spins; in those days, all physicists believed firmly in the symmetry of the laws of Nature. But it was soon clear that the emission of electrons—or beta-rays, as they were called—from nuclei was in a class apart from other atomic or nuclear phenomena. In quantum theory we compute the probability of transition between an initial state and a final state by assuming a certain interaction between the two states; for those beta-transitions, that interaction turned out to be weaker by a factor of many millions than in other phenomena.

In the past decade or so, several other processes which go by weak interactions have been discovered: the spontaneous transformation of a pion (pi-meson) into a muon (mu-meson), or a neutral lambda-hyperon into a pion and a proton. All those transformations happen within less than a millionth of a second, but that is a long time on a nuclear scale, and the interaction between the initial and the final state is found to be in all these cases just as weak as in beta-transformations.

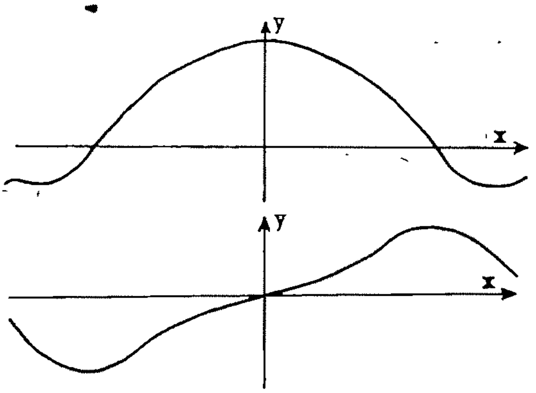

Fig. 3. Graphs representing functions of even parity (above) and odd parity (below)

Of particular interest here were the K-mesons, particles about half as heavy as protons, which were found to break up sometimes into two pions, sometimes into three. This behaviour was in conflict with a well-established rule of quantum mechanics: the rule of 'conservation of parity'. Originally, the parity of a number meant its property of being either odd or even. Later, that concept was extended to apply, not just to numbers, but to mathematical functions. When a quantity y varies in dependence on a quantity x, we call y a function of x, and we can represent a function by a graph. Now if a change in the *sign* of x has no effect on y, we say the function has even parity (or briefly, is even); when it causes y to change sign as well, we say the function has odd parity. The concept is easily extended to the case when f depends on several quantities, say, x, y and z, which may represent co-ordinates in space.

Such functions of space are very important in quantum theory, where they are usually called wave functions, because they resemble waves in special cases. A wave function may have odd or even parity, and it is an important fact that the parity remains unchanged even if the system to which the wave function belongs breaks up (as long as it is not disturbed from outside). This 'conservation of parity' will hold as long as the laws which govern the system are symmetrical, that is, make no difference between right and left, and this was never doubted until about 1956. About that time it became clear that the K-mesons presented a puzzle; it was shown that the system of three pions into which a K-meson can blow up has a wave function with the opposite parity from that of two pions which can also result from the break-up of a K-meson. For a time it was thought that perhaps there were two different kinds of K-meson, having opposite parity; but as the measurements became more accurate and still no other difference between the supposed two kinds could be detected, that idea became unpopular.

In October 1956, T. D. Lee and C. N. Yang, two young, Chinese-born theoreticians working in the United States, published a paper which made history and for which, two years later, they received the Nobel Prize. They looked at the evidence for parity conservation in a variety of processes and found that there was no such evidence for those processes which depended on weak interactions. They proposed some tests, and within a few months they were performed, with positive results. The first tests were quite complex and needed resources found only in a few laboratories; but soon much simpler experiments were devised which proved the simple rule that whenever a particle that has spin is sent out as a result of weak interaction, it tends to spin in a left-handed way about its direction of flight. The particle may be visualized as being like a little left-handed propeller, or that it is fired from a barrel with left-handed rifling, but of course those are just pictures.

Does all this mean that, in her weak interactions, Nature is left-handed, and that her laws are not symmetrical? In a certain sense, yes. But we may widen the concept of symmetry. It has long been known that there is a measure of symmetry between electric charges and the opposite kind. We call them positive and negative, but those are purely conventional labels (and rather unfortunately chosen, since usually it is the 'negative' electrons the movement of which constitutes an electric current). For a time it looked as if the positive charge was definitely associated with the heavy part of matter, the atomic nuclei, and more precisely with the protons which form part of atomic nuclei, and the negative charge with the much lighter electrons. But in 1932 positrons were discovered, which are the positive counterparts of the electrons, and negative protons were first made and observed in 1954. Ever since then, it has been possible to imagine a magic mirror—let us call it a charge mirror—which would leave the shape of an object unchanged but turn all its positive charges into negative ones and *vice versa*. It would even affect some neutral particles: the neutron, which we can image as a small spinning magnet, would be changed into an 'anti-neutron' still spinning in the same direction, but its magnetic poles reversed. In brief, our magic mirror would turn every particle into its anti-particle; but the forces between them would not be changed thereby and the entire system would behave just as before.

But again—just as with a real mirror—this is true only as long as we exclude weak interactions. I said before that any particle emitted as a result of a weak interaction tended to spin to the left about its direction of flight. But if it is an anti-particle that is emitted, then it will tend to spin to the right. That can be verified experimentally: there are radioactive substances that emit positrons rather than electrons, and those positrons are indeed found to spin in the opposite direction.

So the outcome of a weak-interaction experiment is different, according as we change it to its mirror image in an ordinary mirror—which changes right to left—or in our fictitious charge mirror which changes plus to minus. But if we use both mirrors at once then the outcome remains unchanged. To put it in a jocular way: if a physicist had stepped through the looking glass, like Alice, he would be able to tell by measuring the spin direction of electrons emitted in beta-decay, following Lee and Yang; but if at the same time he had stepped into an 'anti-world' where all the particles—including those of his own body—had been transformed into anti-particles, then he could never tell the difference, even with Drs. Anti-Lee and Anti-Yang to help him.

Does such an anti-world actually exist? We do not know yet. When a particle and its anti-particle meet, they annihilate each other and their energy is converted into penetrating radiation. Such radiation is very easily detected, and very little is present on the Earth; hence anti-particles must be rare, not only on the Earth, but all through our galaxy. But we cannot exclude that other galaxies may be made from anti-matter. Our hope of finding out is based on a careful study of those cases where two galaxies collide (a slow process of interpenetration which may last a million years). If one of them were made from matter and the other from anti-matter, an enormous intensity of gamma-radiation would result which we might observe, directly or indirectly; but so far there has been no conclusive evidence for such radiation. So we do not know yet whether Nature as a whole is charge-symmetrical, with equal numbers of galaxies and anti-galaxies, or whether anti-particles are merely fleeting visitors to our world, created by the clash of high-energy particles and annihilated again almost at once.

To sum up: before 1957 the laws of Nature were symmetrical in two separate ways which we may call space symmetry and charge symmetry. Since 1957 each of these symmetries by itself has ceased to be accurate; but they have become wedded into a vaster, more majestic, symmetry, a truly royal wedding the sight of which delights the philosophical mind.

BLUE HAZES IN THE ATMOSPHERE

By Dr. F. W. WENT

Director, Missouri Botanical Garden, St. Louis, 10

THERE are dozens of everyday experiences which can be cited to substantiate the reality and ubiquity of the blue heat or summer haze, which covers, particularly in summer on sunny and windless days, the whole countryside. We must exclude from this enumeration the haze which is produced in cities by 'smog' (partial oxidation products of petrol vapours) or by smoke from fires or industrial activities. But when we are in the countryside far away from cities, a blue haze is still present, usually much bluer than industrial smokes and hazes. Distant mountains are often blue, and may occasionally become almost invisible in a light blue haze. This is perhaps best illustrated with a description of the Tuscan countryside of the sixteenth century, as given by Leonardo da Vinci in his notebooks.

When reading this, one becomes aware of the number of 'Blue Mountains' (for example, in Australia, where blue hazes over the eucalypt forests are very common) and 'Blue Ridges' (in Tennessee, near the 'Smoky Mountains'), all named after one of the most typical aspects of these mountains: that they are usually enveloped in a blue haze or smoke. This haze occurs more commonly in summer, in areas only little populated, at times when no fires occur.

On warm summer afternoons, the Sun's rays breaking between the clouds can be seen as shafts of light against the dark undersides of these clouds. These rays become visible only because they pass through the even mass of haze. When the blue rays have been filtered out of the sunlight, this light becomes more yellowish (in the tropics the Sun is sometimes called the 'copper cad'), or even red (at sunset). These residual red rays produce the *Alpenglühen*, and the deficiency of blue light at sunset makes all our colour pictures taken at that time too yellow.

There is no better way to observe the blue haze than by flying over the countryside. When flying at a few thousand feet altitude, the fields and forests become indistinct near the horizon. The horizon becomes suddenly clear and sharp when the aeroplane rises above the temperature-inversion layer which, during summer, usually lies at 10,000 ft. The horizon is then formed by the clouds which float in this inversion layer with all haze contained underneath, and depending on the density of the haze, the ground surface is remarkably indistinct. Photographs taken from the aeroplane on days with dense haze are lacking in contrast, whereas on hazeless days, similar pictures are brilliant.

There have been a number of suggestions as to the nature of the haze: (1) smoke; (2) dust; (3) water vapour; (4) fog. Even a summary consideration will show that it can be none of these four possibilities. Concerning (1), these hazes are prevalent over moist tropical uninhabited jungles, over cultivated fields in summer, and in general over places without fires. Besides, the smoke plumes of fires or factories can be followed for dozens of miles downwind where they have not merged completely with the surrounding air. Therefore, the even blue haze cannot have its source in fires. Besides, most smoke is yellow or brown, whereas the common summer haze is blue or grey.

Point (2) can also be dismissed easily. The most pronounced haze occurs on quiet days with very low wind velocities, whereas on windy days hazes are less common. Besides, hazes occur already one day after a good rain, and their prevalence over forests and fields speaks equally against dust. Finally, again the blue colour makes dust an impossibility; dust always has the colour of the soil from which it rises.

The possibility that the haze is either (3) water vapour, or (4) fog, can also be ruled out. In the first place, the haze is most pronounced on warm sunny summer days. It never merges gradually into clouds; these remain always distinct. Water does not have any trace of light absorption in the visible part of the spectrum; water vapour as such can therefore never be visible. It can be observed only after it has condensed into droplets, as fog or clouds. But these droplets are at least 5 mμ in diameter and therefore diffract and reflect all colours equally, making them pure white in sunlight. Smaller water droplets, for example, of 1 mμ diameter, are stable only in strongly over-saturated air, and then they would immediately grow to greater size. Only particles or droplets smaller than the wave-length of light will reflect predominantly the blue rays, and such 0·1 mμ or smaller particles give rise to a blue haze.

We come therefore to the conclusion that blue hazes must consist of very minute, submicroscopic particles. This size precludes their formation by fragmentation of larger particles; breaking any matter up into sub-microscopic particles requires enormous forces and fantastic amounts of energy, which are nowhere in evidence on the quiet summer haze days.

The only remaining possibility is that these hazes are formed by agglomeration or condensation of molecules already present in the air. This is only possible, in that size-range, by chemical forces, because the kinetic energy of gas molecules at ordinary air temperatures precludes their condensation.

Fortunately several cases are known in which application of light or chemical energy leads to the condensation of gas molecules to blue hazes. The first of these cases was described almost a hundred years ago by Prof. John Tyndall, of Dublin.

He showed that when a beam of intense light was passed through a tube filled with air containing organic vapours a delicate blue light was emitted by that part of the air through which the light had passed. The lower the concentration of the organic vapours, the more slowly the so-called blue cloud formed, and the deeper the blue colour. On continued irradiation the colour of the blue cloud became lighter until it was whitish. Tyndall also found that the air remained optically empty, and that the blue light emitted by the cloud was polarized, indicating that it was reflected by submicroscopic particles, which obviously grew rapidly until they reflected all wave-lengths, and thus produced a whitish light.

Another case of experimental blue haze formation has been described and demonstrated by Dr. Arie Haagen-Smit, of the California Institute of Technology. When he mixed dilute petrol or olefine vapours with a low concentration of ozone, a blue cloud (with 'smog' smell) formed. This model experiment indicates what is happening in the atmosphere of a city, where considerable amounts of petrol vapours are emitted into the air, and where the energy of sunlight, catalysed by nitrogen oxides, oxidizes the olefines present.

An experiment, similar to that of Haagen-Smit with olefines, shows that volatile organic substances produced by plants behave in the same way as petrol vapours and ozone. When low concentrations of terpenes are injected into an ozone-bearing atmosphere, a blue haze develops. This is clearly shown in the case of dropping a handful of crushed pine needles, or any other aromatic plant material, into a container with ozone. The crushed leaves soon become enveloped in a slight blue haze, which becomes gradually whiter. This behaviour is exactly like that of organic vapours in the strong light of Tyndall's experiment.

Now it can be shown that considerable amounts of volatile organic substances are emitted into the air in sunlight. A pine forest produces quantities of volatile terpenes, such as pinene, which give the forest its piny smell. The fragrance of meadows is also due to volatile organic substances, and so is the aromatic smell of sagebrush and other types of vegetation of dunes and semi-arid regions. The sweet odour of the forest floor covered with autumn leaves is caused by terpenoid compounds, probably derived from decomposing carotenoids.

The amount of these volatile organic compounds produced yearly by all land-plants and their decomposition products is of the order of 10^8 tons. All this disappears again from the air since only a short distance from forest, meadow, or sage, the aromatic odours are no longer noticeable, at least during day. At night, whiffs of strong aromas may drift for much greater distances, but during the day a mechanism exists which removes the odours. This cannot be a simple oxidation to carbon dioxide and water. Even in the plant no enzymes exist which can decompose terpenes after they have been formed.

But through the experiments of Tyndall with light, and those with ozone, we know that partial oxidation can result in condensation of terpenes to macromolecules which refract the blue light. This is the major—and only demonstrable—mechanism by which the molecularly dispersed (and therefore smellable) aromatic compounds in the air can be deodorified. Therefore the same mechanism explains the removal of terpenes from the air, and the formation of a blue haze.

What happens to the particles which cause the blue haze? We can imagine two mechanisms. One is their oxidation to carbon dioxide and water. But in the first instance, they were formed because oxidation did not result in complete oxidation; and the addition products of the ozonides and peroxides produced by light-oxidation of terpenes are scarcely likely to be more oxidizable than the lower-molecular parent substance.

Therefore, the second possible mechanism is that they continue to grow in size and agglomerate into particles which become large enough so that they can be precipitated with rain or snow. They may then change colour from blue to white, grey, brown, or black. Judging by observable phenomena, the last-named seems to be the actual case. Commonly in the afternoon one finds the upper layer of the blue haze layer to be denser and of a grey or black colour. This is only visible when viewing this layer tangentially, that is to say, from an aeroplane flying in the inversion layer. In addition to this one major thin layer of dark colour, there often are several others at about 1,000-ft. intervals; usually there are one to three, but occasionally as many as seven can be counted. The grey, brown or black colour of these layers indicates that the haze particle size is well above 0·5 mμ, very much above that of the blue hazes under the inversion layer. These denser and darker layers of particles must have originated either in the stratosphere, where we do not have sufficient source materials, or in the haze layers below. This means that the sub-microscopic blue haze particles must grow into 1 mμ size particles in the inversion layer, in a relatively short time-period, measured in hours or days. This presents theoretical difficulties, but the facts seem to be clear-cut. There is some direct evidence indicating the transformation of the blue haze into larger particles.

Whenever a layer of convection clouds (strato- or alto-cumulus) accumulates above a blue haze-saturated air layer, certain phenomena can be observed. There is usually a zone of very active cloud appearance and disappearance in the lower end of the inversion layer; and it is exactly in that zone that very thin, dark grey or black wisps of cloud are seen. I call them 'veil clouds' for apparent lack of a specific name. They are clearly defined along the edges of disappearing strato-cumulus cloudlets. Their dark colour is definitely not due to shadows, for they surround a perfectly white cumulus on all sides. Veil clouds are also visible, not associated with any white clouds, but are always very thin, dark in colour, and occur only in the primary and secondary inversion layers. Frequently the lower surface of strato-cumulus consists mainly or partly of veil clouds. Wherever they extend between the strato-cumulus they remain dark in colour, and therefore I believe that a considerable part of the darkness of the lower side of strato-cumulus clouds consists of veil clouds, and that their dark colour indicates that their chemical composition differs very much from water. I suggest that veil clouds associated with alto- and strato-cumulus clouds are accumulations and condensations of the blue haze and therefore that they consist of particles of bituminous or asphaltic materials.

At the size the particles reach in veil clouds they may be effective condensation nuclei, and thus may play a part in cloud formation and even in rain production. They might thus partially replace sodium chloride particles as cloud- and rain-forming nuclei.

Only over vegetated areas are blue hazes and veil clouds observed. Over oceans one can see dilute white hazes, apparently consisting of sodium chloride particles, produced by evaporation of droplets of sea water, splattered by rain or splashing droplets into the air. Over absolute deserts no blue hazes occur (usually only yellow dust layers occur there); but over the creosote-covered California semi-deserts, and over the aromatic Australian interior, blue hazes, of perhaps lower concentration than the hazes hanging over Europe or the Mid-West of the United States, are typical. Blue hazes are typical of all tropical vegetated areas, pine forests, and forests in general.

About the fate of the bituminous and asphaltic particles in the veil clouds and grey or black inversion layers, little can be said. It is almost certain that they return to the Earth's surface with rain and snow, become attached to clay and other soil particles, and thus are either washed down with rivers into delta areas, where they might be the source materials for petroleum deposits, or they become incorporated in humus and peat, and provide the basis for much of the heat content of bituminous coals.

I suggest that the blue hazes and veil clouds play a very important part in the heat balance of the Earth and specifically of the atmosphere. They probably absorb about 20 per cent of all the Sun's radiation reaching the Earth. Therefore they should be considered when calculating the heat conversions near the Earth's surface.

There is another interesting aspect of the veil clouds. They must have a considerable potential heat content. Perhaps they provide not only part of the ions needed to build up the enormous potential differences required for lightning, but they might also provide part of the energy for maintaining the multi-mile long lightning shafts. One of the reasons for suggesting this is that the denser the vegetation and the more terpenes volatilize (due to high temperatures), the more intense the thunderstorms are. Over oceans, over deserts, and over the Arctic, they are absent.

Thus it was suggested that volatilization of terpenes and other plant products results in the production of, first, blue haze, then veil clouds, and finally, bituminous materials which, when returned to the Earth by rain and snow, produce the source materials for petroleum formation. The quantities produced are of the right order of magnitude, and all facts seem to fit into a consistent picture, giving a balanced point of view of many, until recently, unrelated facts.

We need proof of many of the statements and suggestions made here before they can be accepted as any more than a hypothesis. But the hypothesis may serve as a basis for further observations on the hitherto neglected blue hazes and veil clouds.

CYTOPLASMIC PARTICLES AND THEIR ROLE IN PROTEIN SYNTHESIS

THE Colloid and Biophysics Committee of the Faraday Society sponsored an informal discussion on this subject which took place under the chairmanship of Prof. J. A. V. Butler, at the University of Reading during March 28–29. The meeting was attended by approximately 150 people. Twenty-three communications were presented; a considerable number of participants contributed in an informal manner to a stimulating and fruitful discussion.

Studies in the field of protein synthesis, which are designed to elucidate some part of the mechanism by which amino-acids are linked to form peptide chains, have become numerous in the past five years. During this period research in this field reached the stage at which a concern with the development of sufficiently simple biochemical systems suitable for examination *in vitro* superseded the employment of whole organisms for investigations on the incorporation of amino-acids into tissue proteins. A similar trend has also occurred in the field of studies on micro-organisms, the cell components of which can also be fractionated and their metabolic behaviour afterwards examined. In view of the large extent to which amino-acids are incorporated into the proteins of the microsomes they are considered to be an important site of protein synthesis in the cell. In micro-organisms the cell membrane and particles inside it are assumed to be functionally analogous to the microsomal structures found in cells of large organisms. Concurrently with the attention given to the problem of protein synthesis in and by microsomes some research workers have been able to make use of other cytoplasmic components, the mitochondria, to demonstrate that isolated mitochondria are capable of forming their own proteins.

The success of metabolic studies on preparations of cell particles and a correct interpretation of such results often depends on some knowledge of the structure of the cell components. Their examination by physico-chemical and microscopic techniques has yielded useful evidence on their structure as well as on the effect on it of different procedures applied for their isolation. It may here be said that one of the purposes of holding this informal discussion at this time was to provide an opportunity for investigators of the dynamic as well as the structural and morphological aspects of protein synthesis to meet and exchange views.

The opening speaker (C. de Duve, Louvain) rightly dwelt at some length on the limits of resolving power of techniques of cell fractionation. This problem is of particular importance in the examination of the localization of single enzymes, or of enzyme systems. Prof. de Duve discussed the results achieved by his group in applying the technique of centrifugation in a density gradient to the localization of enzymes in tissues. He also reported on another approach, density equilibration in a gradient. This technique makes use of differences in density of particles to separate them in a suitable medium.

Electron microscopy has been of much help in formulating hypotheses which would try to explain some aspects of protein synthesis. It was pointed out by M. S. C. Birbeck and E. H. Mercer (London) that whereas cells such as hepatic cells which synthesize and secrete protein possess an endoplasmic reticulum, that is to say, membranes covered with particles, cells which retain the synthesized protein appear to contain free particles only. Efforts to correlate the site of synthesis with the location of particles or of the endoplasmic reticulum are made difficult by the existence of cell types in which these two points have been observed to be in different parts of the cell.

Many investigators have accepted the particles having a diameter of 15 mμ seen by electron microscopy in the cytoplasm of cells fixed with osmium tetroxide as the structural basis of microsomal nucleo-protein. V. Hanzon (Uppsala) has obtained evidence that these particles may not exist in the living cell since they cannot be detected in pancreatic cells fixed by freeze-drying and subjected to the vapour of osmium tetroxide. These particles seemed to be formed rapidly by a change in the internal milieu of the cell as it is affected by, for example, homogenization or fixation with osmium tetroxide in aqueous medium. Should this observation be confirmed by examination of other cell types it would link up with the results of other investigations which have given evidence that there is no direct relation between the number of visible granules and the content of ribonucleic acid of the microsomes. These ribonucleoprotein particles, now generally referred to as ribosomes, can be examined in the ultracentrifuge as H. E. Huxley and G. Zubay (London) have shown in their studies using *E. coli*. Ribosomes from this organism were found to be able to exist in a number of different stable forms. They could be interconverted by changes in the composition of the medium, particularly in the concentration of free magnesium ions. In addition these workers were able to examine the effect of such changes under the electron microscope. Thus, particles of size 50 *S* have an 'active face' which becomes opposed to another 50 *S* or 30 *S* particle. Examination of 70 *S* particles showed them to be made of two sub-units which resemble 50 *S* and 30 *S* particles, respectively. The pattern shown by ribosomal ribonucleic acid in X-ray diffraction photographs was compared by A. Klug, J. T. Finch and K. C. Holmes (London) to that given by extracted ribonucleic acid. It was considered likely that ribonucleic acid from various ribosomes had its own characteristic configuration; in contrast, the configuration of spherical viruses was probably determined by that of the protein framework.

One effect of chloramphenicol on micro-organisms is to inhibit protein synthesis. S. Dagley and J. Sykes (Leeds) were able to show that in *E. coli* exposure of the cells to chloramphenicol resulted in an accumulation of abnormal species of ribosomes which are apparently useless for protein synthesis. If the antibiotic was displaced from such preparations by magnesium ions, normal ribosomes of size 29 *S* were formed again. The results of an investigation of physical properties of ribosomes from the Jensen sarcoma were reported by M. L. Petermann (New York). The capacity of these ribonucleoprotein preparations to bind protein was found to depend on *p*H or the concentration of magnesium ions, and was observed to be sensitive to changes in ionic strength.

K. McQuillen (Cambridge) was able to report results of an extensive investigation which he and co-workers at the Carnegie Institution of Washington made on time relationships during protein synthesis in *E. coli*. Kinetic studies showed that the smaller ribosomes probably were precursors to the larger. During cell growth the ribonucleic acid and the structural protein of the ribosomes were found to be conserved. Regeneration of ribosomes occurred at an exponential rate in depleted cells; protein, however, was synthesized at a rate proportional to the ribosome content at any time. Evidence was given that radioactivity from amino-acids passed through the ribosomes where it had a transient existence as a protein before it appeared as a soluble protein. The use of ribosomes to study the mechanism of incorporation of amino-acids into proteins has been extended by A. Korner (Cambridge) to preparations obtained from rat liver. These ribosomes prepared by treatment of microsomes with deoxycholate were found capable of incorporating amino-acids on incubation in the presence of adenosine triphosphate and magnesium ions for more than 2 hr.

Most current theories on the mechanism of protein synthesis require the presence of ribonucleic acid from two cytological sources: from the microsomes and from the cell sap (*S*-ribonucleic acid). L. Bosch (Amsterdam) examined the metabolic behaviour of fractions obtained by passing ribonucleic acid through a column of 'Ecteola' resin. Only one of the four fractions obtained by stepwise elution of *S*-ribonucleic acid seemed to be involved in the transfer of amino-acids to microsomes and of radioactivity from phosphorus-32-labelled *S*-ribonucleic acid to microsomal ribonucleic acid. Conversely, only one of three fractions of microsomal ribonucleic acid was found to be capable of accepting radioactivity from phosphorus-32-labelled *S*-ribonucleic acid. The part which *S*-ribonucleic acid might play in protein synthesis was also discussed by V. V. Koningsberger (Utrecht), who reported on the existence in baker's yeast of small, carboxyl-activated peptides originating from activated amino-acids.

F. Gros (Paris) gave an account of experiments in which an alteration in the composition of ribonucleic acid led to modifications in the biosynthesis of proteins. When the uracil analogue 5-fluorouracil was added to growing cultures of *E. coli* some proteins produced were found to have an altered amino-acid composition. The synthesis of new specific protein could also be detected which differed markedly both in biological and physical properties from that produced under normal conditions. These effects appeared to be due to the changes in the ribonucleic acid alone because they also occurred in the presence of thymidine which would make unlikely the incorporation in place of thymine of 5-fluorouracil or its analogues. Another most promising development in the quest to shed light on the role of ribonucleic acid in protein synthesis was discussed by E. M. Martin (London). The use of encephalomyocarditis virus, a small ribonucleic acid virus, which can be propagated *in vitro* within Krebs II mouse ascites cells, may make it possible to demonstrate net synthesis of protein. Viral protein can easily be purified and is then available for further chemical study. This system may also allow the study of the effect of previously modified viral ribonucleic acid on protein synthesis. Preliminary experiments designed to examine the time course of events after infection of the host cell indicated that a marked inhibition of the turnover of ribonucleic acid, as measured by incorporation of 6-carbon-14 orotic acid, was followed by the appearance of most of the virus in the mitochondrial fraction.

The incorporation of amino-acids in the protein of whole microsomes requires the presence of the so-called *S*-ribonucleic acid and of certain enzymes from the cell sap. However, evidence has been produced to show that in some microsomal preparations the addition of these factors may be omitted whereas in others different enzymic extracts can replace these '*p*H-5 enzymes' from the cell sap. M. Beljanski (Paris) showed that a soluble enzyme preparation purified from *Alcaligenes faecalis* stimulated the incorporation of amino-acids into the protein of a particulate fraction from the same micro-organism. The same enzyme preparation was capable of replacing *S*-ribonucleic acid and '*p*H-5 enzymes' in a system suitable for the incorporation of amino-acids into microsomal protein from rat liver. This soluble enzyme preparation did not contain those activating enzymes which catalysed the exchange of adenosine triphosphate with pyrophosphate. However, a transfer in the presence of this enzyme preparation of orthophosphate from nucleoside triphosphate to the homologous diphosphate could be observed for the nucleotides of adenine, guanine, cytosine and uracil. If amino-acids were added to this system the formation of peptides was detected. Although the link is not clear between the presence of enzymes which bring about the above-mentioned transfer of orthophosphate to nucleoside diphosphates, and the ability of this enzyme preparation to stimulate the incorporation of amino-acids into proteins, it was of interest to have a report from J.-P. Zalta (Paris) that he could detect this transfer in certain microsomal fractions from rat liver. They were obtained by the action on whole microsomes of detergents of the polyoxyethylene and arylalkylsulphonate type. These fractions were observed to be capable of incorporating amino-acids into their protein without addition of any enzymic system from the cell sap.

The composition of ribonucleoprotein fractions from the microsomes of rat liver has been investigated by P. Cohn and J. A. V. Butler (London). Extraction with acid of these ribonucleoprotein preparations revealed the presence of basic proteins which, like histones, contained about 25 per cent of basic amino-acid residues but possessed a higher content of acidic residues than histones. Some observations on the process of incorporation of amino-acids into various protein fractions of microsomes indicated that, in contrast to results obtained on the living animal, incorporation under conditions *in vitro* apparently occurred to only a small extent in protein fractions which were not associated with ribonucleic acid in the endoplasmic reticulum. Such a connexion between extent and pattern of incorporation into microsomal fractions and the structural integrity of the membranes of the reticulum, and the possible enzymic inhibition resulting from damage to their lipoproteins were suggested by the experiments of A. von der Decken and T. Hultin (Stockholm). The mushroom poison phalloidin was observed to inhibit, under certain conditions, the incorporation into whole microsomes, but not into a ribonucleoprotein preparation which was derived from microsomes by removal of much lipoprotein material with the aid of a detergent. P. Emmelot and E. L. Bennedetti (Amsterdam) were also able to report an inhibition of the ability of whole microsomes to incorporate amino-acids if the rats had previously been injected with dimethylnitrosamine.

Differences in the requirements for the incorporation of amino-acids into proteins of mitochondria and of microsomes were indicated by the paper of D. B. Roodyn (London). The addition of cell sap or of '*p*H-5 enzymes' was found not to be essential, nor was the process of incorporation sensitive to ribonuclease. The distribution of radioactivity in the protein of various fractions obtained by differential centrifugation of mitochondria disrupted by treatment with a non-ionic detergent was reported. M. V. Simpson (New Haven) has employed mitochondria of both rat liver and calf heart to study the incorporation of amino-acids into cytochrome *c*. Mitochondria from calf heart which maintained their ability to incorporate for periods up to 12 hr. permitted the demonstration of a net increase in cytochrome *c* of about 20 per cent during this time. This synthesis required the supply of energy and the presence of amino-acids. It was also observed that amino-acids were incorporated into total protein of a supernatant fluid obtained from mitochondria subjected to ultrasonic treatment.

Much of the available evidence shows that ribonucleic acid is in some manner concerned with protein synthesis. R. W. Hendler (Bethesda) discussed the possibility that complexes between amino-acids and lipids might be involved in the transport of amino-acids and in protein synthesis. Extraction with organic solvents of the oviducts of laying hens, or of the cell wall and ribosomes of *E. coli*, revealed the presence of amino-acids which were bound to lipids in some way. A possible connexion between protein synthesis and the occurrence of amino-acid-lipid complexes was suggested by the pattern of their chromatographic distribution which was altered by processes which inhibit protein synthesis. The existence of such complexes in *Bacillus megaterium* was reported by G. D. Hunter (London), who suggested that their properties would be consistent with those of a precursor of labelled protein. Other studies gave evidence that the primary site of protein synthesis was present in material which sedimented at comparatively low speeds with the cell membrane, after osmotic lysis of protoplasts. A different approach to the problem of the mechanism of protein synthesis in micro-organisms was reported by B. Nisman and H. Fukuhara (Garches, France), who examined the ability of cell fractions of *E. coli* to incorporate amino-acids. Protoplasts were lysed by treatment with digitonin and then subjected to differential centrifugation. Of the two particulate fractions produced, one contained little and the other no enzymes which catalysed the exchange between adenosine triphosphate and pyrophosphate. Both fractions, however, were capable of readily incorporating amino-acids into protein.

P. COHN

NEWS and VIEWS

British Association for the Advancement of Science

THE July issue of *Advancement of Science* is noteworthy for a number of reasons. Besides articles on a variety of widely differing subjects by leading authorities, it provides enough information about the forthcoming Cardiff meeting of the Association (August 31–September 7) to whet the appetites of those who will be attending. There is to be a whole-day meeting freed from sectional activities when all members will be able to consider the bewildering world food-population problem. Speakers will include Dr. H. C. Wright, Prof. D. V. Glass, Principal W. A. Lewis, Prof. Dudley Stamp, Sir Alexander Fleck, Prof. H. D. Kay and Prof. P. M. S. Blackett. The needs of young people are to be provided for at Cardiff along similar lines to the admirable junior British Association meetings which have been held during 1960 in Birmingham, Belfast and Sheffield. Besides illustrated lectures and a 'brains trust' there is to be a display of work being done in science classes in many Welsh schools.

Ministry of Aviation : Mr. F. S. Barton

MR. F. S. BARTON retired on August 31, thus terminating some forty years in the public service, almost the whole of it in the radio field. He is the eldest son of the late Prof. E. H. Barton, of University College, Nottingham, who was the only Englishman to work with Hertz in Bonn during 1893, work for which he obtained his doctorate of the University of London. F. S. Barton was educated at Nottingham High School and was a foundation scholar of St. John's College, Cambridge. His Cambridge career was interrupted during the First World War by service with the Royal Naval Air Service Radio Experimental Unit at Cranwell. Returning to Cambridge in 1918, he obtained a first class in the Natural Sciences Tripos and rejoined as a scientific officer the Instrument Design Establishment at Biggin Hill, transferring to the Royal Aircraft Establishment, Farnborough, in 1922. Mr. Barton continued to serve there, his chief interest being in radio control of pilotless aircraft and radio research work, rising to be deputy head of the Department, until he left in 1941 to assume the appointment of director of radio engineering to the British Air Commission in Washington. While there, he served on numerous joint British–American committees and was the vice-president during 1943 of the Institute of Radio Engineers. Mr. Barton returned to Britain at the end of 1946 as director of communications development, becoming afterwards director general of electronics research and development at the time of the integration of the Air and Army sides of electronics research and development in the Ministry of Supply. In the autumn of 1955 he was posted to the U.K. High Commission in Ottawa to inaugurate on a more formal basis the interchange of research and development and production information between Canada and the United Kingdom in the defence field. While in Canada he was during 1954–56 the Council representative for the Institution of Electrical Engineers in the province of Ontario.

Mr. C. J. Francis

MR. C. J. FRANCIS has been promoted to deputy chief scientific officer in the Ministry of Aviation and appointed to the post of counsellor (Defence Research and Supply) to the United Kingdom High Commission, Canada, in succession to Mr. F. S. Barton. He joined the Civil Service in 1939, and spent the War years in the Directorate of Communications Development, where he had responsibilities for the ground radar chain, radar navigational aids, and blind-bombing aids. During 1945–54 he was at the Telecommunications Research Establishment (now Royal Radar Establishment), and was divisional leader in charge of development of ground search radars for both military and civil applications. In 1947 he became superintendent in the Airborne Radar Department, and was responsible for research and development of blind-bombing systems, Doppler navigational aids, radar reconnaissance systems, and airborne collision warning; for part of the time he was, in addition, head of the Blind Landing Experimental Unit at Martlesham. In 1954 he was appointed to the British Joint Services Mission in Washington, covering the research and development programmes undertaken by the United States Services in the field of electronics. In 1957 he returned to the United Kingdom as assistant director of electronics research and development (air), which post he will relinquish on taking up the appointment in Ottawa.

Mr. M. B. Morgan, C.B.

MR. MORIEN BEDFORD MORGAN has been appointed deputy controller of aircraft (research and development) in the Ministry of Aviation. In this appointment—which takes effect in September—he will succeed Dr. W. Cawood, whose appointment as chief scientist to the War Office was announced in July. Mr. Morgan, who has been scientific adviser to the Air Ministry since July 1, 1959, was born in 1912 and educated at Rutlish, Merton, and at St. Catharine's College, Cambridge. At Cambridge he obtained first-class honours in the Mechanical Science Tripos and won the Seely Prize in aeronautics in 1934. After an apprenticeship with Mather and Platt, Ltd., he joined the Royal Aircraft Establishment, Farnborough, in 1935, where as a member of the Aerodynamics Department he was engaged on general flight research and development, specializing on problems of stability and control. He was appointed head of the Aerodynamics Flight Section at Farnborough in 1946, and in 1948 was made head of the newly formed Guided Weapons Department. He held this post until January 1954, when he took over as deputy director (air), Royal Aircraft Establishment, a post he held until 1959. In 1957 he was awarded the Silver Medal of the Royal Aeronautical Society for his contributions in the execution and direction of aeronautical research and development. He has maintained a keen interest in flying—he obtained his pilot's '*A*' licence in 1944.

Animal Husbandry at Bristol : Prof. T. K. Ewer

Prof. Tom Keightley Ewer, at present professor of animal husbandry in the University of Queensland, has been appointed to the newly established chair of animal husbandry in the Veterinary School of the University of Bristol. Prof. Ewer, who will take up his appointment early in 1961, was born and educated in England and emigrated to Australia. He graduated in the Veterinary School of the University of Sydney in 1937, having previously obtained the H.D.A. with honours at the Hawkesbury Agricultural College. During the war years Prof. Ewer held appointments with the New Zealand Department of Agriculture and at the Canterbury Agricultural College, and was engaged on work on nutritional and parasitological problems of sheep. In 1947 he was awarded a Wellcome research fellowship by the Animal Health Trust which enabled him to conduct work on ovine rickets in the Institute of Animal Pathology at Cambridge, where he was awarded the degree of Ph.D. Prof. Ewer accepted the appointment he now holds in 1950 and was Dean of the Faculty of Veterinary Science in the University of Queensland for five years. In recent years he has carried out two assignments with the Animal Production Branch of the Food and Agriculture Organization—one in Venezuela, the other in Burma. Prof. Ewer's list of publications is in the field of nutrition in the sheep, his current interest being in the use of sorghum silage and various protein and non-protein nitrogen supplements.

National Academy of Sciences–National Research Council : Appointments

The following appointments as chairmen of divisions of the U.S. National Academy of Sciences–National Research Council have been announced: Prof. Robert C. Elderfield, professor of chemistry in the University of Michigan, as chairman of the Division of Chemistry and Chemical Technology; Dr. Edward P. Espenshade, jun., chairman of the Department of Geography at Northwestern University, as chairman of the Division of Earth Sciences; Dr. Emil W. Haury, professor and head of the Department of Anthropology at the University of Arizona, as chairman of the Division of Anthropology and Psychology; Prof. J. Barkley Rosser, professor of mathematics at Cornell University, as chairman of the Mathematics Division.

The Henry Bryant Bigelow Medal

The first Henry Bryant Bigelow Medal for oceanography has been awarded to the man it honours. Dr. Bigelow, one of America's foremost marine scientists, was among the founders of the Woods Hole Oceanographic Institution. He was its first director, served later as president of the Corporation and is now chairman of the Board of Trustees. He is also professor emeritus of zoology at Harvard University, having taught there for nearly half a century, and is a research oceanographer and former curator of the Museum of Comparative Zoology at Harvard. The Bigelow Medal was established earlier this year by the Trustees of the Oceanographic Institution without the knowledge of their chairman. It is designed with a likeness of Dr. Bigelow on the face and the Institution's first and most famous research vessel, *Atlantis*, on the back. With it go a citation and a cash prize of 2,500 dollars. It is to be awarded from time to time to those "who make significant inquiries into the phenomena of the sea".

Cloud Pictures from Satellite *Tiros* I

The March issue of the *Monthly Weather Review*, published by the U.S. Weather Bureau (on June 15), contains a number of fascinating photographs of cloud systems taken from the satellite *Tiros* during April 1960. The height of the satellite varied between 436 and 460 miles. The photographs are of the cloud systems of temperate-zone depressions over the Atlantic, Pacific and Mediterranean and a tropical cyclone north of New Zealand. The synoptic charts are printed alongside, and the correspondence between the cloud belts and the familiar curved fronts of the weather maps is most striking. The photographs show three major systems, the cloud belts within the systems, and cloud areas within the belts. Both single photographs and mosaics covering large areas are reproduced. There can be no doubt that cloud photographs transmitted from artificial Earth satellites will be a major tool of the weather forecaster of the future.

Intergovernmental Conference on Oceanographic Research

Scientists and government officials from thirty-four countries meeting in Copenhagen during July 11–16 at the invitation of Unesco have agreed to place the whole subject of oceanography on an international footing. Recognizing the importance of oceanographic research for the world as a whole, they recommended that Unesco set up a permanent intergovernment oceanographic commission to organize concerted action by States and by international bodies. Hitherto, the main obstacle to the development of oceanographic research has been the lack of qualified oceanographers. Oceanography has been somewhat of a poor relation among the various branches of science and the number of laboratories and university courses devoted to it is relatively very small. Oceanography now requires large-scale international co-operation. The Conference therefore recommended a number of measures, the chief of which is that an intergovernment oceanographic commission be set up and work with a special Office of Oceanography within the Department of Natural Sciences of Unesco to co-ordinate research on a permanent basis, the Commission meeting, in principle, once a year. This is subject to approval by the 82-nation General Conference of Unesco which meets in Paris next November.

The shortage of oceanographers, considered as one of the main obstacles to oceanographic research, led to the recommendation that the number of fellowships financed by Unesco be appreciably increased so as to offer greater training facilities for such specialists, particularly for those countries in which oceanography is little developed and which wish to participate in oceanic research. Such training should include participation in expeditions organized by the various countries or by Unesco and in short lecture courses or training courses in research institutes and institutions of higher education. Unesco is also asked to organize a conference to discuss the means of developing teaching in the marine sciences in universities. Because the training of oceanographers is so urgent, the Conference recommended that the money proposed in Unesco's budget for 1961–62 for the operation of an international oceanographic vessel be used for other training activities. Other steps towards international co-operation recommended by the Conference in a series of resolutions are the standardization and intercalibration of methods and equipment—such as the sizes and types of nets and the techniques used in the collection of plankton; the collection and exchange of oceanographical data; and the organization of joint research programmes in specified regions by groups of countries, such as that planned for the Indian Ocean. The Conference also asked Governments and international organizations to take immediate steps to prevent pollution by radioactive material and to intensify their research programmes in this field.

Cosmic Radiation Studies in South America

THE Latin American Council of Cosmic Radiation, with members from Argentina, Bolivia, Brazil, Chile, Mexico, Peru, Puerto Rico and Venezuela, met during August 1–3 at the Centro Brasileiro de Pesquisas Físicas in Rio de Janeiro. Observers representing the International Union of Pure and Applied Physics and Unesco were also present. The meeting was called and organized by Unesco's Centre of Scientific Co-operation for Latin America, Montevideo. The Council decided to organize a brief course of three weeks duration and seminars to be held in Mexico beginning late in June 1961. The latter will cover the following topics: composition of primary cosmic radiation, physics of interplanetary plasma, solar physics, time variations, extensive air showers and theory of geomagnetic effects. An effort will be made to secure the participation of physicists from other than Latin American countries in these seminars. The Council hopes to send through proper channels suggestions for experiments which can be made aboard space vehicles and artificial satellites. Members of the Council attending the Rio meeting were Prof. José Manzano (Argentina), Dr. Narayan Nerurkar (Bolivia), Prof. Georges Schwachheim (Brazil), Prof. Gabriel Alvial (Chile), Prof. Manuel S. Vallarta (Mexico) and Prof. Manuel Bemporad (Venezuela). Observers present were Prof. Gabriel Fialho (International Union of Pure and Applied Physics), Dr. Angel Establier (Unesco), Prof. Gleb Wataghin (University of Turin) and Prof. Gianpietro Puppi (University of Bologna). Prof. Vallarta acted as chairman.

Fossil Meteorites

ADDITIONAL information is provided by B. I. Vronsky (*Priroda*, 9, 116; 1959) on the probable 'fossil meteorite' (*Nature*, 184, 1026; 1959). This meteorite was discovered in November 1957 in the valley of a small river, Zarya, a tributary of the Susuman River, itself a tributary, Berelekh, Magadan district of Siberia. This meteorite, which received the name 'Susuman' and which weighed about 19 kgm., was discovered at the base of an alluvial deposit consisting of gravels and mud. Thus, in age it is assumed to be Post-Glacial and about 15–20 thousand years old. It is only now that it has been made known that in this region, a few years previously, two similar meteorites have been discovered in similar situations. Thus, the iron meteorite, 'Mal'dyak', was discovered at a depth of 4·6 m. in gravels of the River Mal'dyak situated 28 km. to the south of Susuman. In 1941 the iron meteorite 'Burgavli', weighing 24·9 kgm., was found in the gravels of the River Adachi, a right tributary of Yana River. These three meteorites are now being studied in detail.

Industrial Health in Britain

MR. R. CARR asked in the House of Commons for a statement about the development of industrial health services in Britain. The Minister of Labour, Mr. E. Heath, said in reply on July 25 that the development of such services is under consideration by the Industrial Health Advisory Committee. Legal requirements safeguarding the health of industrial workers are contained in the Factories Acts and Regulations, which are constantly being revised and extended. In addition, many firms voluntarily provide medical and nursing services, and to encourage more employers to do so, a booklet is to be published later this year giving details of the cost of some of these services, together with the views of management and work-people about them. Group schemes have also operated successfully in a few places with special circumstances, such as Slough and Harlow, and we now need to explore the possibilities of establishing group schemes in areas of a different kind. Another need is the further use and development of industrial hygienic services to carry out chemical, physical and biological tests where special hazards exist or are suspected. The Minister said that arrangements are being made to set up an organization to collect information about existing facilities regularly and to make it available to employers. He had discussed further action with the Nuffield Foundation, which has had considerable experience in promoting industrial health schemes, and the Trustees of the Foundation are allocating £250,000 for the further development of group industrial health schemes and industrial hygienic schemes. The money will be used to assist practical schemes which promise to become self-supporting, and in selecting such schemes the Foundation would work in the closest co-operation with the Ministry of Health.

Preparing Teachers for Health Education

HEALTH education is not always recognized as a discipline of its own and given its appropriate place in the training of teachers. A report of a joint World Health Organization/Unesco Expert Committee (World Health Organization: Technical Report Series. No. 193. 1960. 1*s*. 9*d*.) provides a flexible framework of guiding principles for such training, which should take place not only through courses of instruction but also through the teacher's actual mode of life in his training institution, his contact with student health services, and his experiences when practising teaching. Health education in schools should be based on the health needs and interests of the children, the teacher having opportunities for imparting it, both directly and by the part he can play in the school health services and in planning a healthy school. To enable him to make the most of his opportunities he must have some knowledge of growth and development, personal and community health, health practice in schools, and methods of health education. The report discusses these subjects, the future teacher's life as a student in relation to his opportunities for health work and to health services for students, practice teaching and the education he acquires as a fully-fledged teacher. Other sections deal with planning of training for teachers in health education, the desirability of one person in each training institution being responsible for co-ordination of courses and activities in health education, and possible future national and international developments, studies and research in the subject.

The Research Defence Society

The Research Defence Society policy of presenting factual information in readily assimilable forms on 'explosive' topics like immunization, vaccination and animal experiments continues with an excellent pamphlet on vaccination against whooping cough, diphtheria and tetanus (*Conquest* Pamphlet No. 11. Research Defence Society, 11 Chandos Street, Cavendish Square, London, W.1. 6*d*.). The methods of immunization against these three conditions and the problems arising in connexion with the procedure are considered together for two reasons : the first is that protective injections against these diseases are now usually given earlier in life than are most others ; and the second that these substances are often given all together as a mixture, thus minimizing the number of injections required. The value of the pamphlet is that in no cases are dangers minimized or awkward questions evaded. These are put simply, answered objectively, and include information which indicates where preventive medicine may not always have been effective. The pamphlet should be widely distributed in maternity and child welfare clinics.

Genetic Recombination in *Salmonella typhimurium* occurring during Transmission of Colicinogeny

An interesting item in the annual report of the Lister Institute for 1960 is an investigation by Drs. Ozeki and Howarth into the recombination of chromosomal genes in systems in which colicinogeny is being transmitted. Their results indicate that, in about one pairing in a million, genes believed to be located in the bacterial chromosome (for example, genes regulating various biosynthetic steps and a gene for resistance to streptomycin) undergo recombination. Recombinants can be detected in small numbers whenever colicinogeny-I is being transmitted at high frequency, and in larger numbers when colicinogeny-*E*1 is also being transmitted. Many pairs of genes cannot be simultaneously transduced by a single phage particle, probably because they are not close together in the bacterial chromosome, only a very small fraction of which can be enclosed within a single phage particle. A number of crosses involving such pairs of apparently unlinked genes were made by the newly discovered method of hybridization, and in every instance a fraction of the recombinants was found to have received both pairs of genes concerned from the strain which was transmitting colicinogeny. This suggests that, in this new kind of hybridization, either the whole or at least a large fraction of the chromosomes of the transmitting strain is enabled to recombine with the chromosome of the acceptor strain, in contrast to the situation in phage-mediated transduction. It seems likely that the new method of hybridization may prove of great value in determining the arrangement of the genes along the whole length of the *Salmonella* chromosome, a problem which could not be investigated with the previously available method of hybridization by phage-mediated transduction.

Nature Conservation in East Anglia

A booklet, "Nature and Conservation in East Anglia", produced on the occasion of the Duke of Edinburgh's visit on July 8, 1960, describes briefly the work of the Conservation Corps of the Council for Nature in clearing scrub for the National Trust at Wicken Fen, the Nature Reserve at Havergate Island and Orfordness, and the work of the Field Studies Council at Flatford Mill (pp. 16. London: The Council for Nature, 1960). This attractive booklet also gives brief accounts of the work of the Council for Nature and the Royal Society for the Protection of Birds as well as of the Nature Conservancy, and is well designed to promote public awareness of our heritage of wild life and the need to conserve it more effectively.

Darwin's Notebooks

In Part 3 of "Darwin's Notebooks on Transmutation of Species", Sir Gavin de Beer shows that the contents of the "Third Notebook" owe nothing to Malthus's work (*Bull. Brit. Mus.* (*Nat. Hist.*), Historical 2, No. 4. London, 1960). "It is therefore of great importance to note that Darwin hit on the principle of natural selection independently. After a consideration of changes resulting in the formation of new species, he wrote : 'All this agrees well with my view of those forms slightly favoured getting the upper hand and forming species'. " Darwin himself realized the historical importance of these lines, because at a later date when he looked through his "Notebook", he wrote at the head of it : "Towards close I first thought of selection owing to struggle". How the stimulus of Malthus's book put Darwin on the scent of natural selection is well brought out in this edited version of his "Third Notebook".

Lancaster Royal Grammar School Natural History Society

The extra-mural duties involved in running a society in a grammar school is an arduous task for the masters and boys concerned. Lancaster Royal Grammar School may be rightly proud of its Natural History Society, which has recently celebrated its twenty-first anniversary. The society periodically publishes a magazine, and, in the ninth issue of *The New Biologian*, the contributions include articles by the masters and boys, records of the Society's activities, etc. The articles include descriptions of biological stations and field study centres and show the value of these in awakening genuine interests among the participating students. One clear difference emerges from the journal and those of natural history societies established in boarding schools: almost invariably in the latter their journals contain some record of original work by boys. Biology masters in grammar schools would do well to examine them.

The Korsakov Journal of Neuropathology and Psychiatry

Arrangements have been completed for the quarterly publication of an English translation of selected papers from the well-known Soviet periodical, *The Korsakov Journal of Neuropathology and Psychiatry*. The English edition will begin with the first issue of 1960, and will contain English abstracts of all articles not translated. The translated journal will be published by Pergamon Press, and Dr. W. Ritchie Russell (Oxford) will act as English editor.

American Society for Cell Biology

A group of cell biologists met in New York on January 9 and again on May 28 of this year, and organized a new society, the purpose of which is to further the development of cell biology and to improve communication among scientists representing diverse disciplines. Membership is expected to include biochemists, biophysicists, cytologists, histologists, microbiologists, physiologists and others having in common an interest in the cell. The organization has been named the American Society for Cell Biology. Applications to join the Society should be sent to Dr. Montrose J. Moses, Box 2982, Duke University School of Medicine, Durham, N.C. Membership is not restricted to residents of the United States.

Maccabæan Prize and Medal

THROUGH the generosity of the Maccabæans, the Faculty of the History of Medicine and Pharmacy of the Worshipful Society of Apothecaries is able to offer an annual prize of not less than 25 guineas, with a bronze medal, for the best original essay on a subject connected with the history of medicine or pharmacy written by an undergraduate or graduate less than thirty years of age. Further information can be obtained from Dr. F. N. L. Poynter, The Wellcome Historical Medical Library, 183 Euston Road, London, N.W.1.

Research in Biochemistry and Allied Sciences

A COLLOQUIUM on the Organization and Financing of Research in Biochemistry and Allied Sciences is to be held under the joint auspices of the Biochemical Society and the British Association, in the Physiology Institute, Newport Road, Cardiff, on September 7 (the last day of the British Association meeting) at 2 p.m. It is expected that the following speakers will take part: Prof. John Pryde (chairman), Prof. A. Haddow (British Empire Cancer Campaign), Dr. F. J. C. Herrald (Medical Research Council), Sir William Slater (Agricultural Research Council), Mr. C. Jollife (Department of Scientific and Industrial Research), Dr. G. F. Marrian (Imperial Cancer Research Fund), Prof. F. C. Happold (University of Leeds), Dr. F. A. Robinson (on behalf of industry), Dr. J. B. Bateman (U.S. Embassy, London), Prof. A. Neuberger (St. Mary's Hospital Medical School). The Colloquium is being organized jointly by Dr. K. S. Dodgson, Physiology Institute, University College, Newport Road, Cardiff, and Dr. W. J. Whelan (meeting secretary of the Biochemical Society), from whom particulars can be obtained.

The Night Sky in September

FULL moon occurs on Sept. 5d. 11h. 19m. U.T., and new moon on Sept. 20d. 23h. 13m. The following conjunctions with the Moon take place: Sept. 1d. 08h., Saturn 4° S.; Sept. 12d. 01h., Aldebaran 0·2° S.; Sept. 13d. 10h., Mars 5° N.; Sept 23d. 22h., Venus 3° S.; Sept. 27d. 10h., Jupiter 5° S.; Sept. 28d. 14h., Saturn 4° S. In addition to these conjunctions with the Moon, Venus is in conjunction with Spica on Sept. 20d. 22h., Venus being 3° N.; and Mercury with Spica on Sept. 26d. 16h., Mercury being 1° N. There will be a total eclipse of the Moon on September 5 and a partial eclipse of the Sun on September 20–21; both eclipses will be invisible at Greenwich. There were two eclipses in March of this year, making in all four in 1960. As is usually the case when four eclipses occur in a year, they take place in pairs about six months apart. Mercury and Venus are too close to the Sun for observation. Mars rises at 22h. 15m., 21h. 50m. and 21h. 20m. at the beginning, middle and end of the month, respectively. It is in Taurus at the beginning of September and moves into Gemini on Sept. 20. Mars is rapidly becoming brighter, its stellar magnitude being +0·5 and its distance from the Earth 106 million miles in the middle of the month. Jupiter sets at 22h. 40m., 21h. 50m. and 20h. 55m. on September 1, 15 and 30, respectively; it is in Ophiuchus, but conditions are not very favourable for observation. Its stellar magnitude is −1·8 and its distance from the Earth on September 15 is 470 million miles. Saturn is in Sagittarius, east of Jupiter, and sets at 0h. 00m., 23h. 05m. and 22h. 05m. at the beginning, middle and end of the month, respectively. It is stationary on September 15 and afterwards resumes eastward motion among the stars. Its stellar magnitude is +0·6 and its distance from the Earth in the middle of the month is 890 million miles. Occultations of stars brighter than magnitude 6 are as follows, observations being made at Greenwich: Sept. 9d. 4h. 45·1m., ξ^1 Cet. (*D*); Sept. 12d. 1h. 14·3m., 89 Tau. (*R*); Sept. 12d. 1h. 21·3m., σ^2 Tau. (*R*); Sept. 13d. 1h. 05·0m., 117 Tau. (*R*). *D* and *R* refer to disappearance and reappearance, respectively. The autumnal equinox occurs on Sept. 23d. 01h.

Announcements

MR. M. D. TAYLOR, of the Department of Chemical Engineering, King's College, University of Durham, has been awarded a CJB Scholarship, of the value of £450 per annum, for two years in the first instance. This scholarship scheme, administered jointly by Constructors John Brown, Ltd., and the Institution of Chemical Engineers, is to encourage research in chemical engineering and, in particular, in chemical plant design.

AN International Symposium on Photoelasticity will be held during October 29–31, 1961, at the Illinois Institute of Technology, Chicago, Illinois. Further information can be obtained from Dr. Paul D. Flynn, Illinois Institute of Technology, Chicago 16, Illinois.

A SYMPOSIUM on Redox Processes will be held at the Chemical Laboratories, University of Allahabad, under the auspices of the Chemical Research Committee, Council of Scientific and Industrial Research, India, during January 1961. Further information can be obtained from Dr. Satya Prakash, Department of Chemistry, University of Allahabad.

A CONFERENCE on Diffraction will be held during November 9–11 at the Mellon Institute, Pittsburgh, Pennsylvania. Sessions will be devoted to metals and alloys, instrumentation, structures, polymers and fibres, refractories, electron probes and electron diffraction. Further information can be obtained from L. F. Vassamillet, Mellon Institute, 4400 Fifth Avenue, Pittsburgh 13, Pennsylvania.

THE Institution of Electronics, with the co-operation of the Hull Electronic Engineering Society, is to hold an Electronics and Instruments Exhibition and Convention at the Farmery Hall, George St., Hull, during the period September 28–30. Admission will be free of charge and by tickets obtainable from exhibitors, or from W. Birtwistle, General Secretary, Institution of Electronics, 78 Shaw Road, Rochdale, Lancs., or from C. W. Wyan, Honorary Secretary, Hull Electronic Engineering Society, 2 Lockton Grove, Calvert Road, Hull, Yorks.

ERRATUM. In the communication entitled "Structure of β-Acylacrylic Acids", by Prof. Nils Hellstrom, in *Nature* of July 9, p. 146, the description of the ordinate of Fig. 1 is incorrect; for "Acid/sodium hydroxide" read "Sodium hydroxide/acid".

THE FOURTH INTERNATIONAL GOITRE CONFERENCE

THERE is a growing body of opinion in favour of replacing the large international conferences, attended by three or four thousand people, by smaller gatherings of an international character, and devoted to more specialized topics. At such meetings there should be better opportunity for expert discussion of communications, less overlapping of programmes and, above all, a chance of seeking out and talking with specific participants. Confirmation of the correctness of such expectations was afforded by the very successful meeting of the Fourth International Goitre Conference held in London during July 4–8. In all, about 600 endocrinologists, clinicians and biochemists, drawn from more than forty countries, took part. More than a hundred papers were delivered, and a book of abstracts of about 500 words each, in four languages, was provided at the time of registration.

A very large part of the subject-matter reported at the Conference was devoted to endemic goitre, and papers were read which surveyed its incidence in various parts of the world, the genetic aspects of the subject, and the part which goitrogens and other factors might play in its etiology. That iodine deficiency, in the opinion of Perinetti *et al.* and Kicic *et al.*, is the most important cause of endemic goitre was shown by the reliable effects which iodized salt had brought about in the disappearance of the condition in such different areas as Mendoza in Argentina and Gornja Josanica in Yugoslavia. On the other hand, Kilpatrick *et al.* suggested that iodine deficiency probably plays only a part in the development of goitre in an area to the west side of Sheffield, which was compared with a coastal district near Edinburgh. Although the iodine content in the water supply in the two districts is not dissimilar, there was a higher incidence of goitres in Sheffield. More fish was consumed in Scotland. It was further noticed that there was a definite familial linkage in the disease. An examination of the iodine content of goitrous thyroids did not reveal consistently low values as compared with normal thyroids. Observations of the seasonal incidence of goitre in sheep and cattle and the similar seasonal variation in anti-thyroid activity of milk (even in dried milk) suggests that though iodine may play a part in the incidence of goitre in the Sheffield area, goitrogens may also be a contributory factor.

Similar views were put forward by Costa *et al.*, who conclude that endemic goitre is a process which goes beyond mere alteration in thyroid function and that it is not a simple adaptation by the gland to iodine shortage. In a very careful examination by Koenig in Switzerland of nineteen endemic cretins, ranging in ages between 46 and 93 years, a number of interesting facts arose. It is difficult to find cretins born in Switzerland after 1910, which is at least ten years prior to the inception of iodine prophylaxis. Results of determinations of protein-bound iodine and the uptake of thyroidal iodine-131 show wide individual variation. In most cases these values were low, but in some they were normal and in others high. Some cretins responded well to exogenous thyroid-stimulating hormones, while others did not. The basic metabolic rate was a most unreliable indication of the state of affairs.

Cassano *et al.* believe that iodine deficiency may arise from excessive renal loss. They found that a high rate of excretion of iodine normally occurs in puberty and pregnancy and, significantly, in Cushing's disease and acromegaly, suggesting a hormonal basis for the increased renal excretion. The hormone most active on renal clearance of iodine is aldosterone. In any areas where iodine deficiency is likely, increased renal clearance of iodine, as in pregnancy and puberty, might favour the development of goitre.

A number of *Brassicae* are goitrogenic when fed to animals. Astwood *et al.*[1] isolated L-5-vinyl-2-thio-oxazolidone (goitrin) from yellow turnips, but this cyclized derivative of an *iso*thiocyanate does not exist as such in the plant but is formed enzymically from progoitrin, identified by Greer as a mustard oil glycoside. It is now reported (Greer *et al.*) that the conversion to goitrin can be accomplished by micro-organisms in the animal gastrointestinal tract. Both cooked and raw brassicaceous vegetables are therefore potentially goitrogenic, the effect being an iodine-blocking one.

Endemic goitre is not always associated with a deficiency of iodine in the soil and a relation to pasture has been suspected. Thus, in Tasmania endemic goitre occurs and it has been shown that cows fed on the brassica 'chou-moellier' secrete an active goitrogen in their milk which is consumed in quantity by school children. Peltola reports a somewhat similar situation from Finland, where endemic goitre areas exist. Recently published researches of Bachelard and Trikojus[2] go far to elucidate this problem. They find the turnip weed *Rapistrum rugosum*, which grows abundantly in certain areas of Australia, to contain a glycoside of cheiroline (γ-methylsulphonylpropyl-*iso*thiocyanate). Cheiroline had a variable goitrogenic effect when administered to rats, suggesting its possible transformation into an effective goitrogen in the animal body. Incubation of cheiroline with cows' ruminal contents afforded *sym*-di-cheiroline thiourea $(CH_3SO_2[CH_2]_3NH)_2C=S$. This interesting transformation may occur more generally with *iso*thiocyanates and be of importance in bringing about endemic goitre.

Dimitriadou *et al.* believe that there may be a defective synthesis and storage of fully iodinated hormones in some cases of non-toxic goitre and that this might be due to a defective iodinating mechanism. By means of their 'supplemented iodine-131 test' it was possible to calculate the amount of iodine-127 available to the thyroid, the rate at which iodine-131 became fixed organically into the various iodinated amino-acids in the gland, and also to estimate the size of the thyroid iodine stores. Results indicated little difference in urinary iodine excretion between patients with thyrotoxicosis, those with non-toxic goitre (with or without avid uptake of iodine) and euthyroid individuals. Stores of iodine compounds in the thyroid were diminished in cases of non-toxic goitre and the rate of transfer of iodine-131 into heavily iodinated compounds, that is to say, diiodotyrosine and the iodinated thyronines, was slower in such persons. This defective or slowed iodinating mechanism can be compensated for, however, by iodine supplements even though, by normal standards, these persons were not deficient of iodine in the diet.

A number of authors reported studies in which family pedigrees were examined to discover the incidence of abnormal thyroid behaviour. Fraser *et al.* and Thould and Scowen reported on the condition known as Pendred's syndrome, the main features of which are bilateral deafness, observed early in life, and goitre developing from about eight years onwards. The defect, which is probably congenital lack of a peroxidase enzyme system in the thyroid, results in inadequate organic binding of iodine. The condition is rare, and genetic data suggest that the syndrome is inherited in a recessive manner.

Other genetic studies were reported on simple goitre. One pedigree of 250 individuals was studied (Van Wyk *et al.*) which suggested that the occurrence of goitre in this family was a simple dominant trait which is more commonly overt in the female. Serologically there was a characteristic abnormality which consisted of a protein-bound iodinated constituent migrating electrophoretically with the albumin fraction. Other studies in a different family provided evidence of defective peripheral dehalogenation of iodotyrosines.

Elucidation of the process of biosynthesis of its hormone by the thyroid gland has proved to be a peculiarly baffling problem. The process may be divided into the three stages of concentration of iodide from the blood (the 'trapping' mechanism), iodination of thyroglobulin and release of thyroxine or triiodothyronine from the gland. Such a subdivision, although convenient, is somewhat arbitrary since it becomes increasingly clear that the metabolism of iodine must be considered within the thyroid gland as a whole.

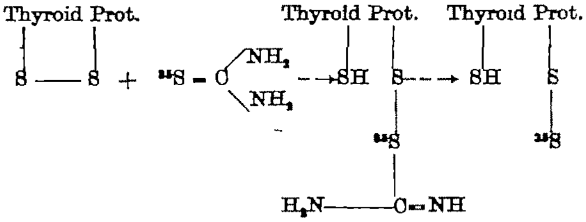
Thiocyanate and perchlorate are both known to prevent the accumulation of radioiodine by the thyroid. Wollman and Reed reported experiments designed to ascertain whether thiocyanate can, in addition, affect the iodination process and involving measurements of the binding-rate and thyroid/serum ratio (T/S) of injected radioiodide computed for different levels of serum thiocyanate. If two thyroidal compartments, an iodinating and a non-iodinating, respectively, were envisaged and the concentration of radioiodide in the latter was assumed to parallel that of serum, binding-rate constants became independent of serum thiocyanate-levels, consistent with the hypothesis that thiocyanate acts solely by decreasing the concentration of radioiodide at the binding site.

Perchlorate is excreted virtually unchanged (Lewitus *et al.*). Administration of $K^{42}Cl^{36}O_4$ showed that it is distributed in the body as is the iodine ion, being similarly concentrated in the thyroid gland. The supposed antagonism between perchlorate and iodide is of a competitive nature. These two ions have nearly the same ionic volume. Monofluorosulphonate, difluorophosphate and fluoroborate also have approximately the same ionic volume and are isoelectronic with perchlorate, and trial shows that they also inhibit the uptake of iodine by the thyroid. These studies lead to the conclusion that the 'trapping mechanism' may be merely a specifically adapted protein with a spatial arrangement that will chelate those ions which will fit into its spatial structure.

The synthesis of thyroglobulin in the mouse has been followed autoradiographically after injection of labelled leucine (Nadler *et al.*). Maximum activity was seen in the epithelium within 0·5 hr., followed by a decline as activity rose in the colloid (maximum in 35 hr.). These results are interpreted as indicating synthesis of a pre-thyroglobulin in the epithelium followed by secretion as thyroglobulin into the colloid, where it is iodinated prior to breakdown and release of thyroxine and amino-acids. The number of cells in the epithelium controls the rates of these processes. De Groot reported upon the early stages of *in vitro* hormonogenesis in sheep thyroid slices and in living rats. A homogenate of the thyroid tissue was separated into mitochondrial, microsomal and soluble fractions which were then analysed. Soluble fraction protein-bound iodine-131 as per cent of total protein-bound iodine-131 increased rapidly, then plateaued and was apparently all thyroglobulin. No thyroxine was identified in slice homogenates. It seems that in the iodination of thyroglobulin, iodine-131 may be transferred from a particulate fraction.

There is still much discussion concerning the possible role of a thyroid peroxidase in oxidizing iodide to iodine available for iodination. This chemical reaction can occur *in vitro* and therefore seems attractive, but it will be recalled that, among others, Glock[4] has severely criticized the evidence purporting to show the presence of a true peroxidase in the thyroid gland. Alexander reports that thyroid and salivary gland homogenates oxidize iodide in the presence of hydrogen peroxide added as such or generated by auto-oxidation of flavin. Catalase or anaerobiosis prevents flavin activation. The iodine formed by oxidation will iodinate tyrosine and to a lesser extent histidine, but the presumed natural acceptors, thyronine and di- and tri-iodothyronine, are *not* iodinated by this system.

That biological iodination may, in fact, be brought about by a different mechanism is suggested by a most interesting communication from Maloof and Soodak. These authors had previously demonstrated the desulphuration of sulphur-35-labelled thiourea by a cytoplasmic particulate system of thyroid. Thiouracil and thioacetamide are similarly desulphurated, the products being about 50 per cent protein-bound sulphur-35, 27 per cent thiosulphate, 10 per cent sulphate and 10 per cent an unknown compound. The protein-bound sulphur-35 is non-dialysable and stable to acid, but 80 per cent of it is displaced by such alkaline reagents as cyanide, sulphite, sodium hydroxide or by thiols such as cysteine, reduced glutathione and diethyldithiocarbamate. The desulphuration of thiourea is strongly inhibited by sulphite and cyanide, nucleophilic anions which are known to split disulphide bonds forming a thiol and an S-alkyl thiosulphate or alkyl thiocyanate, respectively. Using $Na_2{}^{35}SO_3$, it is found that it also forms protein-bound sulphur-35, which is quantitatively and qualitatively similar to that arising from labelled thiourea. The results suggest that both react with thyroid protein disulphide bonds forming a new mixed disulphide linkage as follows :



Free sulphydryl groups do not play a part in the desulphuration of thiourea since pre-incubation with SH reagents is not inhibitory. Parallel observations on the iodination reaction in this *in vitro* system suggest that a disulphide bond may be involved in the formation of an active iodinating intermediate. Hence, cleavage of an S—S bond in thyroid tissue by thiourea may be a factor in the inhibitory action of this compound. The desulphurating effect appears to be specific since it did not occur with liver tissue preparations.

Anti-thyroid drugs are not only of great therapeutic value, but also the study of their action continues to throw light upon the mechanism of biosynthesis of thyroxine, as the last-mentioned contribution clearly shows. For the medical treatment of thyrotoxicosis in the United States, according to McClintock and Gassner, propylthiouracil, 1-methyl-2-mercaptoimidazole and 5-iodo-2-thiouracil are most commonly used, while the British 'Carbimazole' has only been introduced there during the past year. The trend is to use these drugs for pre-operative preparation although their use as the sole method of curative therapy still has adherents. The first three have been compared for involutional activity. 5-Iodo-2-thiouracil appeared superior and gave less trouble during subsequent surgery. All the compounds are, however, associated with toxic reactions (4–8 per cent). It may be mentioned in this connexion that one of the advantages of 'Carbimazole' is its comparatively low toxicity.

The mode of action of anti-thyroid drugs has been investigated by Rimington. Recent work shows that where thiol ⇌ thione tautomerism is possible, involving carbon and nitrogen, compounds exist mainly in the thione form (hydrogen on nitrogen not on sulphur); configuration may be 'fixed', however, by alkylation. Using 'Neo-mercazole' ('Carbimazole': 1-methyl-3-carbethoxy-2-thioglyoxalone) for standard reference, a series of compounds were compared including derivatives of 3-mercapto-1,2,4-triazole and the alkyl-fixed thiol and thione form corresponding to 'Neo-mercazole' itself, namely, 1-methyl-3-ethylglyoxaline-2-thione and 2-ethylmercapto-1-methylglyoxoline. None was as potent an anti-thyroid in rats as 'Neo-mercazole' and the thione configuration appeared to be that responsible for anti-thyroid action. Measurement of the inhibitory effect of these drugs upon a horseradish peroxidase system *in vitro* showed no correlation with anti-thyroid activity.

Mayberry and Astwood have used propylthiouracil to study the intrathyroidal metabolism of iodine in rats. The distribution of iodine-131 in controls 24 hr. after dosing was triiodothyronine 2·6 per cent, thyroxine 21·2 per cent, iodide 2·7 per cent, monoiodotyrosine 25·2 per cent, and diiodotyrosine 42·4 per cent, and these proportions varied little during six days while 53 per cent of the iodine-131 left the gland. In the propylthiouracil-treated group, 92 per cent of activity left the gland in the same time, while the proportion of thyroxine steadily diminished. If recycling of iodine-131 was prevented by a large dose of iodide following the isotope, rate of loss of iodine-131 was only slightly greater than in the controls and the distribution was similar except for a slow drop in monoiodotyrosine. These results suggest that propylthiouracil not only blocks iodination but may also inhibit coupling of iodotyrosines.

The lipid metabolism of the thyroid has been investigated using phosphorus-32. Experiments on rats of depletion of sialic acid, iodine-131 and iodine-127 from the gland indicate that the concentration of the former affords a measure of the thyroglobulin content. Histochemical methods have been used in investigations of prolonged dietary iodine deficiency and of normal and pathological glands. Lindsay and Jenks studied a number of dehydrogenases, diphosphopyridine nucleotide and triphosphopyridine nucleotide diaphorases, monoamine and cytochrome oxidases and found most of these enzymes increased in animals treated with propylthiouracil, but greatly decreased after hypophysectomy or thyroid feeding. Tricarboxylic acid cycle enzymes are present in thyroid glands, but in lower concentrations than in sheep liver (Dumont). They are not inhibited by anti-thyroid drugs and are raised in glands from treated thyrotoxicosis patients. Blood pyruvic acid is high in toxic goitre but normal in non-toxic goitre (Gasiorowski). It remained high after attainment of the euthyroid state.

The firmness of binding of thyroxine in sera has been measured by determining the proportion held back on a suitable resin; enhanced binding is found in myxœdema, after propylthiouracil and in pregnancy but weak binding in hyperthyroidism (Mitchell *et al.*). Attention was, however, directed by Hamolsky *et al.* to the effects of factors such as carbon dioxide tension, buffers and *p*H on thyroxine binding in sera. At *p*H 8·6 an irreversible increase in binding occurs. The pattern of thyroxine binding in normal and pathological conditions has been the subject of several investigations. The pre-albumin shows a greater elective affinity for triiodothyronine than for thyroxine (Andreoli *et al.*).

The discovery of triiodothyronine has turned attention to the deiodinating enzymes and the metabolism of the thyroid hormones. Thus, Lissitzky *et al.* reported that thyroxine bound to specific binding protein is protected from deiodination and that in cells there is competition for thyroxine between deiodinase and thyroxine bound protein.

The tadpole has long been used for the study of thyroxine. With its development into a frog, concomitant alterations occur in responsiveness to thyroid hormone and the manner or rate at which it is metabolized (Galton and Ingbar). The results presented are consistent with, but do not prove, the hypothesis that hormonal response is linked to hormonal degradation. The fate of the doubly labelled sulphuric ester of triiodothyronine in the rat is rapid hydrolysis followed by deiodination. It appears to be either a storage or transport form of the hormone (Roche *et al.*). Radioactive 'Triac' and 'Tetrac', the acetic acid analogues of triiodothyronine and thyroxine, respectively, are found by Green and Ingbar to be metabolized differently in man.

Peripheral biochemical anomalies as well as thyroidal disturbances are thought to be present in sporadic cretinism from studies by Klein of the half-value times of thyroxine metabolism.

The relationship of pituitary to thyroid function has been studied by Becker *et al.* Patients with active or inactive Graves's disease did not show an immediate decrease of thyroid function following total hypophysectomy.

One of the most difficult conditions commonly associated with thyrotoxicosis to understand, and also one of the most unpredictable in its course, is exophthalmos. A number of interesting papers were read on the subject. Bartels and Irie showed, by studying patients suffering from severe progressive exophthalmos, that there was no close relationship between the development of the condition and the functional state of the thyroid or the type of treatment given for hyperthyroidism. Hitherto the course, degree and severity of exophthalmos have often been regarded as being influenced by the type and extent of the treatment offered for thyrotoxicity. A significant minority of patients developed exophthalmos before hyperthyroidism, and in five cases of severe exophthalmos no hyperthyroidism was noted at any time.

Dobyns described the use of fish (*Fundulus heteroclitus*), for the measurement of the level of an exophthalmos-producing substance in serum. Only in patients with active, progressive exophthalmos was exophthalmos-producing substance clearly demonstrable. Condliffe *et al.* provided evidence, from work with ion-exchange chromatography, that thyroid-stimulating hormone and an exophthalmos-producing substance are separate entities.

Contributions to our knowledge of the relationship between pituitary and thyroid activity, as well as a further understanding of those substances circulating in the blood stream which affect the activity of the thyroid gland, both in health and disease, were made by a number of authors. Two important papers (Purves and Adams, and J. M. McKenzie) described an abnormal thyroid-stimulating agent present in the blood of hyperthyroid persons. It appears not to be present in normal persons; the substance differs from normal thyrotrophin, for example, in the duration of its effect on the thyroid of guinea pigs and mice. It is active far longer than thyroid-stimulating hormone. The substance is active in hypophysectomized animals, thus demonstrating that it acts directly on the thyroid. The amount in serum appears to be correlated more closely with the degree of exophthalmos present than the severity of hyperthyroidism. Halmi *et al.* showed that thyroid-stimulating hormone stimulates rapidly the output of iodide from the thyroid, but the uptake of iodide more slowly.

El Kabir reports a reliable assay method for thyroid-stimulating hormone based on release of iodine-131 in incubated guinea pig thyroid slices. Generally speaking, thyroid-stimulating hormone values were high in patients with thyrotoxicosis and untreated primary myxœdema, whereas in exophthalmic ophthalmoplegia the values did not differ appreciably from normal.

Hellman *et al.* pointed out that apart from the differences in thyroxine-levels to be found in myxœdema and hyperthyroidism, there were also profound differences in the metabolism of androgens. If the thyroid dysfunction is corrected, disturbances in the androgens return to normal. Androsterone, of which low levels are found in hypothyroidism and high levels in hyperthyroidism, can be shown to produce to some extent the actions of thyroxine itself (thyromimetic effect).

No significant thyroxine formation was found by Taurog *et al.* in thyroidectomized rats. On the other hand, large daily injections of iodide had a stimulatory effect on growth. Since no thyroxine can be detected in the plasma, the possibility must be considered that iodide itself may have a thyroxine-like effect on tissues when given in high concentrations.

The connexion between serum cholesterol-levels, hyperthyroidism, hypothyroidism and the incidence of myocardial infarction has fascinated many, and a number of papers were devoted to these subjects.

One of the most interesting concepts which has arisen in recent years in connexion with the etiology of disease is that of auto-immunization, namely, the production by the body of antibodies against one of its own tissue components. That this could be a mechanism has often been suspected, but not clearly demonstrated, until Doniach and Roitt's work on Hashimoto's thyroiditis. Positive serological reactions can be obtained with the serum of such patients. Trotter and Belyavin observed complement fixation reactions between thyroid extracts and sera from patients of nearly all cases of Hashimoto's thyroiditis. The antigen is probably derived from the thyroid cells and appears to reside in the microsome fraction. Most cases of spontaneous myxœdema and about one-third of patients with thyrotoxicosis afford serum with a relatively low titre, as do occasional cases with non-toxic goitre, thyroid carcinoma or normal subjects. This cellular antigen can be detected in extracts of all types of thyroid, but is most abundant in thyrotoxic glands. Fixation of complement by the antigen and its corresponding antibody may be prevented by an inhibitory factor. The serum from patients with Hashimoto's disease commonly contains antibodies also against thyroglobulin. These are demonstrable by precipitation reactions and are distinct from those to the 'cellular antigen'.

A striking objective demonstration of the cytotoxicity of Hashimoto's sera was presented in a film by Pulvertaft *et al.* Primary cultures of human thyroid cells put up in fresh Hashimoto's serum showed few, if any, surviving cells at 18 hr. Substitution of Hashimoto's serum for normal serum in an 18-hr. old culture was followed by immediate darkening of the filamentous mitochondria and their gradual dissolution followed by rapid death of the cell. On the other hand, cultures grown for 36 hr. appeared to remain unaffected. The factor in Hashimoto's serum is thermolabile and specific; it does not kill all cells in a dense culture. Somewhat conflicting evidence was presented by Irvine, who argues that Hashimoto humoral antibodies are of secondary etiological importance. He considers that the basic pathology of Hashimoto's disease may be damage to the basement membrane, possibly due to cell-bound antibodies. Humoral antibodies, secondary to the escape of colloid, would then be an effect, rather than a cause, of the disease. However, since serological reactions are frequently demonstrable in thyroid disease, even in a small percentage of cases of unequivocal thyrotoxicosis according to Alexander *et al.*, and since some patients without Hashimoto's disease have a few clinical features of thyroid over-activity, screening tests for Hashimoto's thyroiditis should always be undertaken.

Two papers were presented in which the incidence of cancer was related to the use of radioactivity therapeutically. Winship and Rosvoll discussed an attempt which had been made over twelve years to examine the past history of children who, prior to the age of fifteen years, developed cancer of the thyroid. Where it has been possible to interrogate the parents of the children very fully, in 81 per cent of the cases there was a history of irradiation having been given therapeutically for a variety of reasons. Commonly, X-ray therapy had been given to try to treat an enlarged thymus. Sometimes similar treatment had been given for enlarged tonsils and adenoids; in others, for hæmangiomata and nævi. The latent period for the development of malignancy appears to be 7–12 years, and in most cases 400–700 r. had been given. The most common type of carcinoma encountered was the papillary type. Another investigation of a not dissimilar character was reported by Pochin. Careful analysis of the actual incidence of leukæmia in patients treated with radioactive iodine for cancer of the thyroid, when compared with the incidence of the disease in the healthy population at large, suggests that leukæmia may have to be regarded as a calculated risk (even if only a small one) when this treatment is used for thyroid cancer. Pochin, however, suggested that when smaller dosages are given for the treatment of thyrotoxicosis, the present known incidence of leukæmia does not appear to be greater than that which could have been said to have arisen by chance. Nevertheless, it is clearly desirable to watch this situation carefully and to extend observation over a longer period.

Ackerman *et al.* reported a simple and accurate test for the diagnosis of thyroid cancer. This consists of giving orally 500 mc. of phosphorus-32. Twenty-four hours later, multiple counts are taken of the radioactivity from suspicious nodules. In six cases uptake of phosphorus-32 was increased markedly. These were afterwards shown to be malignant tumours. It was very interesting to find that one case of Hashimoto's disease also suggested malignancy by this test. Thirty-four negative tests were produced and in all those operated upon (22), except one, benign tumours were diagnosed.

It is twenty-two years since the last International Goitre Conference, and although striking advances in both knowledge and technique have occurred during this time, it will be apparent that many fundamental problems still remain unresolved.

The late Edwin Ramsdell had prepared an address which was read at the opening of the conference. In it he reminded the members that at the third conference there had been no mention even of anti-thyroid drugs, let alone of radioactive isotopes. How completely the position has changed will be evident from the wide compass of topics dealt with in 1960.

THE BRITISH COMPUTER SOCIETY

HARROGATE MEETING

SOME 400 delegates attended the second annual conference of the British Computer Society, held at Harrogate during July 4–7. The president, Dr. M. V. Wilkes, noted with satisfaction that the Society, with one annual meeting behind it, was indeed flourishing.

In his opening address, Dr. Wilkes announced the formation of an International Federation of Information Processing Societies, in which the British Computer Society would represent the United Kingdom. The Federation has elected its secretary-treasurer (A. Speiser, Switzerland), president (I. Auerbach, United States) and vice-president (A. Walther, Germany), and has announced that its next conference will be in Munich in September 1962.

Dr. Wilkes referred to the activities of the publication committees of the British Computer Society, and especially to the technical committees on automatic programming. He thought that scientific auto-coding was now generally accepted, but that the break-through in auto-code language for commercial applications, the results of which could be devastating, was still to come. One of the most important current problems was that of data-transmission, and he compared the rather slow teleprinter circuit, with difficult checking facilities, with the telephone circuit with forward error-detecting codes and automatic repeat when necessary. An interesting point was that 100 per cent accuracy is not essential, the aim being to make the transmission of information as accurate as any further processing thereof. He envisaged the less-pecunious universities ringing round to their more fortunate brethren, sending their problems by telephone to the fastest and cheapest service. Again, however, he warned that the solution of the problem, though imminent, was not yet effected.

The second session discussed a common computer language. C. Strachey (formerly of the National Research Development Corporation) outlined the problems arising in the construction of such language and its advantages to programmers, and mentioned important advances made by the United States in the technique of 'list-processing'. He made a plea for humans to regard their time as valuable, and to refrain from relapsing into slavery to the machine. R. Brooker (University of Manchester) spoke in technical terms of some recent work in constructing translating routines, carried out at Manchester, for any 'computer-oriented' language, and reported success with regard to the autocodes of *Pegasus* and *Mercury*. These methods apparently need a machine with a fairly large store, though K. Tocher (United Steel) reported success in devising restricted autocodes for smaller machines.

Business applications also have their auto language, and R. Paine (I.C.T.) outlined the desirable features of such a language and some attempts made to meet them. He warned that management cannot yet dispense with its programming staff, that the language of the accountant is not yet that of the computing machine, and envisaged the evolution of long-hand and short-hand versions of the language. This contribution included the comments that a computer conference might be described as a "meeting of contiguous word-noises", and that machine manufacturers' advertisements of business computer autocodes rarely err on the side of modesty.

At about this stage one notes with sorrow the transformation of certain features of the English language, and too often its mutilation which, in these vulgar times, seems to accompany the development of any new scientific field, and in which computer terminology is second to none. One finally applauded the question, "What exactly, please, is a programmer ?", and listened with regretful admiration to the chairman's "Since it is now time for coffee, I shall have to treat that question as rhetorical !"

The next session was also concerned with language and general-purpose programmes, this time for market research (A. Douglas, University of Leeds, and R. Cook, Elliott Bros.), which provided facilities for receiving and verifying data, forming frequency tables, and printing results in any desired format, and in general statistical survey work (F. Yates, Rothamsted), and success was reported with several of the smaller machines.

Small computers were also featured in a symposium on their use in a variety of problems covering clerical processes, production-control in a medium-sized factory, an analysis of a reasonably complicated hydro-electric system, and stock control in a shoe factory. This sequence of thoughtful, well-presented papers seemed to leave the audience rather bemused. Did they, one wonders, ponder on the remarkable advances in the past decade when machines like the Stantec *Zebra*, ICT 1201, Elliott 402 and 802 and Ramac 305 can now properly be described as small, or were they shattered with the perfect simplicity of a data-transmission system in which a gamekeeper reads water-levels once a week, cycles ten miles, and sends off postcards ?

S. Clarke (Elliott Bros.) and S. Gill (Ferranti) gave accounts of recent respective visits to the U.S.S.R. and the United States. Clarke reported great Russian interest in British computing equipment and their own assessment of a four years lag behind the West. He described some Russian machines, none of which has a rapid access store of more than about 2,000 words, and noted that their present main interests were in automation and language translation. He found little effort in general data-processing and commercial applications other than in pay-roll work. The Chinese have apparently made a perfect copy of one of the largest Russian machines in one year, indicating perhaps the shape of things to come.

Gill found advances in the United States rather disappointing in actual machines, and thought that new British projects such as the *Atlas* have no clear trans-Atlantic superior. In programming techniques parallel operation and time-sharing are all the rage, but enthusiasm for international machine languages like *Algol* (scientific) and *Cobol* (commercial) are somewhat on the wane. For example, no *Algol* compiler is yet working efficiently for any machine in the United States, and university research is concentrated on more general studies in the theory of computer programming. He commented on the work of Hao Wang, an Oxford mathematical logician at present in America, who on an International Business Machines computer proved 350 significant theorems in "Principia Mathematica" in 8½ min., exclusive of printing time. Wang has remarked on the great significance for mathematics of the cross-fertilization of 'inferential calculus' and computing machines. Here is certainly a fascinating field of research, needing for its success mathematicians of the highest competence and machines of a size greater than any at present installed in a British university.

Attention was directed in one of the sessions to the organization of computing centres in universities (R. Buckingham, University of London) and industrial establishments (A. Bagshaw, Ferranti). University work covers a very broad field, mainly scientific, with consequent advantages for the 'open shop' method of working, in which most users write, test, and perhaps run their own problems. This, of course, is not always possible; the 'unflappability' of the Chancellor of the University of Oxford would, one imagines, be tested severely, and unfairly, by his first few attempts at programme checking. Commercial centres have similar problems except that scientific work is beginning to be swamped by general data-processing calculations, with consequent greater economy in more operator-controlled machine running. This tendency will intensify when 'time-sharing' machines come into general use. A. Beaven (National Computer Research) had a different problem of organization, involved in the training of operators and the writing of programmes to check and correct data, derived from automatic paper-tape punches attached to accounting machines, for input to a computer, such data amounting to nearly three-quarters of a million paper-tape characters a month.

Time-sharing was put into practice when the numerical analysts, in surprisingly large numbers, discussed some new techniques for applying predictor-corrector formulæ in initial-value problems and for the iterative solution of non-linear boundary-value problems in ordinary differential equations, the determination of latent roots of matrixes when the parameter appears in non-linear form, and the behaviour of the remainder term and other aspects of Gauss-type quadrature formulæ. These papers comprised a small but fairly representative sample of current research in 'computer-oriented' numerical analysis. At the same time, the larger group studied problems of simulation in chemical plants, power stations and other works, the computer being used to make adjustments to the detailed process, using a 'mathematical model' and a statement of objectives, in order to increase efficiency and output.

On the last morning, D. Polley (Ministry of Pensions and National Insurance) and Col. L. Slater (Royal Army Pay Corps) gave accounts of respective progress in the installation of data-processing schemes for insurance records and for the payment of the military. In both cases the machinery required seemed to be substantial, with reels of magnetic tape and a 'Xeronic' printer on one hand, to cope with the processing, in a six-monthly period of each year, of thirty million tax-reduction cards, and on the other an International Business Machine 705 computer, 1,401 tabulation system and a staff of 100. Soldiers must have their pay, and one sympathizes with the problem of maintaining continuity in reimbursement and record in the process of changing from manual to automatic operation.

Finally, a small symposium (which might well have shared time with numerical analysis so that all, including myself, could have heard about simulation) discussed techniques of accounting, in wholesale and retail branch control, in 'invoicing' in general, in the paper industry in particular, and in banking. Here, it seems, the problems of programming are trivial compared with those of deciding the factors which should be taken into account (as, for example, the loss of weight in stored cheese), and of collecting all the parts into a coherent logical entity.

The organization of the meeting was good and its after-effects promising, since those who could not attend will apparently have a chance to study at more leisure at least some of the main contributions, which will be published in the *Computer Journal*. We lacked only sunshine (perhaps mercifully in the Harrogate Sun Pavilion) and, as usual, time for adequate discussion. The Pavilion was just large enough to accommodate the full audience and reception and entertainment, provided by the Mayor, and a small exhibition of computing mechanisms, models and plans, provided by the leading British manufacturers, in an atmosphere at once both sufficiently formal and intimate.

L. FOX

THE MUSEUMS ASSOCIATION

THE sixty-sixth annual conference of the Museums Association was held in the city of Stoke-on-Trent during July 4–8, by kind invitation of the Corporation and University College of North Staffordshire. Dr. W. E. Swinton, of the British Museum (Natural History), presided over some 330 delegates.

The conference was warmly welcomed at this its first visit to Stoke by the Lord Mayor, and in his presidential address Dr. Swinton dwelt on the present plight and difficulties of the museum movement. He welcomed increased grants made by the Treasury to the national museums, and the provincial museums through the scheme administered by the Victoria and Albert Museum. He also looked forward to the founding of further regional councils based on the existing prototype in the south-west of England. Dr. Swinton deplored the absence of travelling museums in rural districts, for they had been so eminently successful in the United States, and he felt convinced that they would supply a real need in Britain. Dr. Swinton, taking his text from the underground geology in the area, then discussed the injection of art and science into industry and the way in which literature and the arts had influenced the industrial life of the city.

The presidential address thus paved the way for the main discussion of the conference, which concerned itself with the relations of museums and industry, introduced by Sir Colin Anderson, Mr. Ian Cox, Mr. John Moores and Sir John Wedgwood. All speakers agreed that with the competition of television and shop displays the standard of exhibition in museums should be high and modern in outlook. It was also felt that the displays should be stimulating and give pleasure as well as instruction. Curators should study the methods of salesmanship. In the same way that no shop would freeze its windows, museums must be prepared to change their displays as often as possible. Museums, on their part, can do much to stimulate new designs and help to maintain high standards of craftsmanship.

Another important discussion concerned the purchase of art objects for museums. The speakers included Sir Anthony Blunt, Dr. Trenchard Cox, and Messrs. G. L. Conran, Terence Mullaly and Hugh Scrutton. It was generally agreed that directors should make more frequent contact with the London market, although even then purchases were to a great extent a matter of chance with either local or national opportunities. It was also stressed that rare and expensive objects should not be the desiderata of museums but they should endeavour to create an individual character.

At the annual general meeting it was decided to increase institutional members on the Council from three to six and to request nominations for these from regional organizations.

Dr. D. B. Harden (London Museum) was elected president and Mr. Phillip James was confirmed in his office as secretary. It was decided to hold the next conference at Plymouth during June 19–24, 1961.

Social functions included an informal reception at Keele Park by invitation of the University College, a reception and dance by invitation of the Lord Mayor and tours of the Arnold Bennett country, the Potteries, Kedleston and Dovedale. Official visits were also made to the local museums.

THE BRITISH STEEL CASTINGS RESEARCH ASSOCIATION

THE progressive growth of one of the youngest research associations was marked recently by the open days held during June 28–30 by the British Steel Castings Research Association at its Research Station in Sheffield. The open days were attended by 546 representatives, principally from member companies and from users of steel castings.

The opening of the Association's Research Station was noted in these columns (*Nature*, 180, 221; 1957). Within three years the Association has found it necessary to add a further 10,000 sq. ft. to its accommodation, while its staff has increased in this period from forty-nine to seventy-six. The increased accommodation has provided substantially more space in laboratories devoted to chemical analysis, metallurgy, sand testing and mechanical testing. The machine shop has been correspondingly enlarged, and new laboratories have been provided for radiography and the handling of isotopes used in investigations employing radioactive tracers and for the analysis of gases in steel. The experimental foundry has also been enlarged to the extent of 50 per cent in floor area, providing floor space for the installation of a 56-lb. vacuum melting furnace, for pilot plant studies of dust and fume collection equipment and for the study of foundry plant and equipment on a scale approximating to that of installations in production foundries. The total cost of the extensions together with the equipment installed therein has been £60,000, bringing the total cost of the Research Station to £165,000 within a period of four years. The present income of the Association is a little more than £100,000 per annum. The number of steel foundries in Great Britain is not large, and the present subscription income represents an average subscription of £1,000 a member. That the Association can maintain such a high level of subscription and has, in fact, recently increased the subscription rate by nearly 10 per cent is indicative of the importance that the industry attaches to its co-operative research.

The demonstrations of the Association's work, which were on show at the open days, illustrated very well the point that many of the problems associated with the production of steel castings are non-metallurgical in character. A large proportion of the research effort is concerned with moulding materials and with the interactions that occur at high temperatures between molten steel and the sands and other refractories from which moulds are made. One of the Association's major problems has been to evolve quantitative techniques for the measurement of such phenomena as the friability of moulding sands on drying, the erosion of moulds that occurs when molten steel flows over the surface, the penetration of molten steel into the interstices between sand grains and the 'flowability' of moulding sands, that is, the ease or difficulty with which they may be compacted in narrow pockets, etc. Techniques have been evolved for these and similar measurements; for example, it has been possible, by using a test casting in which a controlled air pressure is applied to the liquid steel, to synthesize in a casting only 15 in. high the ferrostatic head experienced at the bottom of a casting 20 ft. in height. This technique has greatly facilitated the study of the penetration of liquid steel into moulding materials.

Much attention has been given to the development of mould paints and washes, and new formulations based on the dispersion of refractory particles in alginate suspensions have been developed which produce paint films that do not crack on drying or when molten steel is poured into the mould. These are a considerable advance on commercially available washes and are being applied on an increasing scale in the foundries of the Association's members.

The engineering section of the Association devotes considerable effort to studies of plant and equipment used in foundries and is actively engaged on investigations of factors affecting the performance of moulding machines and shot-blasting equipment. Studies are also being made of both wet and dry methods for the reclamation of used foundry sand. Here the problem is to remove from sand grains the layer of dead bonding clay to enable the sand to be re-bonded for cores and moulds.

From its inception the Association has always maintained a lively interest in problems relating to industrial health in foundries. Its recent activities have included the development of an exhausted fettling bench which combines control of fine dust with a substantial reduction in noise pressure-level when castings are cleaned with pneumatic chipping hammers. These benches are now being made by two manufacturers.

Studies are also being made of atmospheric pollution from foundry steel-making furnaces, and a survey has recently been completed of the fume emission of arc furnaces varying from 30 cwt. to 80 tons capacity and from side blown ('Tropenas') converters.

The Association attaches considerable importance to liaison with its member companies, and they are regularly visited by senior members of the staff to discuss aspects of the Association's work ripe for development and also to advise on technical problems arising in production. Conferences and discussion groups are also organized both on a national and a regional basis, and during the past year an average of eight representatives per member company participated in these meetings. The Association also organizes short training courses for representatives of members on subjects such as moulding sand control, steelmaking techniques, etc. During 1961 a training course is to be organized on work simplification in foundries.

The seventh annual report of the Association has recently been published, and in presenting this to the annual general meeting on June 28, Dr. R. Hunter (Clyde Alloy Steel Co., Ltd.), the chairman of the Association's Council, invited members' attention to notable features of the report. He directed special attention to the expanded programme of liaison with industry referred to above and also to the establishment of a joint committee, the Steel Castings Development Committee, between the Research Association and the trade association, the British Steel Founders' Association. The function of this Committee is to disseminate data designed to promote the greater use of steel castings, and the Research Association has in hand a substantial programme of work for this Committee to determine properties of steel castings on which data are now lacking. A useful start has also been made in the provision of lectures and lecture material for presentation to engineering societies and engineering departments of technical colleges.

A. H. SULLY

CULTURE, SOCIETY AND HEALTH

DURING June 1–3, 1960, the Division of Anthropology of the New York Academy of Sciences and the Research Institute for the Study of Man jointly arranged a conference on culture, society and health. Among the many interesting papers was one dealing with cancer frequency and socio-cultural factors and another which examined the frequency of coronary artery disease in population groups. The study of socio-cultural factors in cancer was carried out by Walter B. Quisenberry, Division of Preventative Medicine, State Department of Health, Honolulu.

The population of Hawaii is made up of approximately 35 per cent Japanese, 23 per cent Caucasians, 18 per cent Hawaiians and part-Hawaiians, 12 per cent Filipinos, 6 per cent Chinese and 6 per cent others such as Koreans, Samoans, and Puerto Ricans.

Quisenberry's investigations showed that the incidence of stomach cancer is highest in Japanese men. There are probably many socio-cultural factors such as dietary habits which play a part in causing this. Primary cancer of the liver, however, is most frequent in Filipino men. Filipino men probably eat foods which are higher in carbohydrates and lower in protein and vitamin B_1 than those of other ethnic groups.

Filipino and Japanese men have the lowest incidence of lung cancer in Hawaii; Japanese men and Filipino men have probably smoked fewer cigarettes over the years than Caucasian men. The Caucasian breast cancer rate is five times the Japanese rate; Japanese women have been slower in giving up the nursing of children than have the Caucasians. Cancer of the large intestine is more frequent in Caucasian women than in any other ethnic groups; the diet habits and, perhaps, the bowel habits of Caucasian and Japanese women are different.

Cancer of the prostate gland is about nine times more frequent in Caucasian men than in Japanese men; the socio-cultural factors which may be responsible for this great variance in incidence of prostatic cancer may be related to differences in love-making and mating habits of the two ethnic groups. Cancer of the nasopharynx is most frequent in Chinese; it is possible that there is irritation of the nasopharynx in Chinese from hot liquids such as tea.

Cancer of the uterine cervix is most frequent among Hawaiian and part-Hawaiian women; because Hawaiians are by nature phlegmatic, the women probably do not receive as good care following pregnancies as do women of other ethnic groups. Skin cancer is most frequent among Caucasians; this is due probably more to differences in skin pigmentation than to socio-cultural factors.

Quisenberry suggests that some of the ethnic differences in the frequency of cancer may disappear with the integration of different racial groups in Hawaii. The changes may bring about either lower or higher incidences of cancer. For example, cancer of the breast seems to be increasing in Japanese women due to the stopping of nursing of children.

The study of coronary artery disease was carried out by David M. Spain of Beth El Hospital, New York, and indicates that there has been a significant increase in the incidence of coronary atherosclerotic heart disease over the past twenty-five years in the United States. The possible environmental factors associated with this increase have been evaluated in relation to the possible common denominators in the environment believed to be associated with the reported low incidence of coronary artery disease in the South African Bantu, the Eskimo and the Chinese.

The preliminary findings of factors thought to be associated with coronary atherosclerotic heart disease in a study on several thousand males of the same ethnic origins from the New York metropolitan area were presented to illustrate the complex problems involved in the validation of the significance of such data. Such questions as standards of measurement, criteria for diagnosis, body build, occupational physical activity, obesity, hypertension, serum lipids, urinary oestrogens, diet and smoking habits were analysed while the limitations of studying coronary artery disease in living population groups, as well as the fallacy of generalizing from the findings in autopsy populations, were clearly shown.

THE STRENGTH OF SOLIDS

PROF. A. H. COTTRELL in his discourse to the Royal Institution on June 15, entitled "The Strength of Solids", emphasized the importance of this subject in engineering, and also in the functioning of the bones and muscles of the human machine he distinguished between two kinds of strength—that limited by plastic yielding and that limited by fracture. The manner in which a material fails depends on the relative values of strength against such ductile or brittle failure.

Those brittle materials which have very high inter-atomic forces and which should therefore have very high strengths are nevertheless weak due to the presence of small cracks or notches which act as stress concentrations. When a relatively flawless specimen of such a material can be prepared, it is found to have a strength that approaches the theoretical value. It is not, however, practicable to make such specimens in large enough size or sufficient quantity to be of use for structural components in engineering.

The ultimate strength of a ductile material depends on the stress at which a neck begins to form in a tensile test, that is to say, on its plastic behaviour, which involves the yield stress and work-hardening characteristics. An over-hardened material will not be ductile. The plastic deformation of crystalline solids is due to the sliding of crystal layers over one another. Slip over any layer is not simultaneous, but is due to the movement of a dislocation line which separates the slipped from the unslipped portion. Ordinary solids in engineering contain many sources of dislocations so that they are intrinsically soft and ductile. The vast amount of plastic deformation permissible enables a ductile material to absorb the energy of shock loading and is a protection against fracture. Strengthening is achieved by placing obstacles in the paths of the dislocations—by alloying, heat treatment, neutron bombardment, etc. If, however, too much strengthening is given the plastic yielding strength may exceed the fracture strength and the material would become brittle.

Steel, though normally ductile, is a borderline case, low-temperatures or impact loading or a combination of these factors can cause brittle failure—a phenomenon which has led to many engineering failures.

Prof. Cottrell concluded with some remarks on fatigue failure, which is not yet fully understood. It is observed that in fatigue, plastic deformation becomes concentrated on a few slip planes, so that slip bands develop and then initiate cracks. It would appear that this is a process of local work softening.

K. J. Pascoe

RESEARCH IN CASE STUDIES

THE use of case studies in management training is well acknowledged as an important method of linking practical problems with management theory. However, as a training technique it is still unfamiliar to many people; and many who have heard about it have had no experience of it. Such was the basis and cause of a proposal by the South London Committee during the 1959–60 session to explore the methods of using case studies. This promised to bring significant benefits to members of the British Institute of Management in the South London area.

The effective use of a case-study discussion demands considerable skill on the part of the chairman if it is to have a real impact on every member of a case-study discussion group, from the vociferous to the reticent, and worth-while contributions from all are to be obtained. On account of this, the Committee felt that it should obtain guidance and training from an authoritative source. Co-operation was therefore established with Miss Avice V. Turnbull, research officer on case studies, Royal Institute of Public Administration, and special lecturer in management studies, Northampton College of Advanced Technology, London, and Mr. Z. M. T. Tarkowski, adviser on training, and special lecturer in management studies, Northampton College of Advanced Technology, London, who have done a considerable amount of work in this field.

The South London Committee convened a Case Study Group, at the meetings of which, at monthly intervals, various case studies were considered. The bulk of those so far discussed were from a series produced by Mr. Tarkowski, which give a representative sample of management situations, each in a typical British context. The way discussion went was analysed afterwards, under the leadership of Miss Turnbull.

The wisdom of selecting this approach became apparent early on in the series of meetings of the Group. Postmortems brought out the many interrelated points which have to be recognized and brought to bear on each other by the chairman. The effect of the size of the group, of a time limit, of the extent of the previous experience of the use of case studies, the attitudes of members, the need for the leader to draw members into the discussion and to encourage cross-fertilization of ideas without imposing on the group, are some of the many points which were discussed and which call for skilful leadership.

The reaction of the group depended upon the nature of the case study. If, at first sight, a specific management problem was apparent, or if the case study described a dramatic situation, such as a conflict of actual decisions taken, there was a tendency to examine the obvious problem and to suggest a satisfactory line of action which could be the next step to be taken in the situation. Where the management problems were more intangible and demanded a deeper analysis of individual characters, and of the situation, the more limited approach was replaced by a broader consideration of the personalities and the influences of the background in the work situation which caused a strained atmosphere. In fact, more than one problem can be isolated in these case studies, depending on the perception of individual members of a group. Practice in this type of analysis gave more satisfaction to the members of the Group. At the last meeting held, a case study already previously discussed was re-examined, and comparisons were made with the first discussion. These brought out the wide range of issues which can be illustrated by a single case study, and how diverse two discussions of the same case study can be.

Co-operating with Mr. Tarkowski and Miss Turnbull, several members of the Group have appeared as 'characters' in case study exercises held as part of a course at the Northampton College of Advanced Technology. The object of these exercises is to make the case studies more vivid and realistic, to bring out subtle issues of verbal communication and to give members of the group practice and experience in day-to-day interviews and conversations, which form a large proportion of a manager's work. So far as is known, no course on quite similar lines has been developed elsewhere.

The South London Committee has now arranged a week-end conference on "Research Necessary for the Preparation and Use of Case Studies : Some Recent Work and Prospects for Further Developments in Great Britain", to be held during October 7–9 at the British European Airways Staff College, East Burnham, Slough, Bucks. Further information can be obtained from A. E. Hoult, South London Branch, British Institute of Management, c/o Management House, Fetter Lane, London, E.C.2.

THE RESEARCH COUNCIL OF ALBERTA

THE fortieth annual report of the Research Council of Alberta, covering the year 1959, contains lists of advisory committees and their membership and of the staff of the Research Council besides a list of publications for the period 1955–59 (pp. v+54. Report No. 79. Edmonton: Research Council of Alberta, 1960). During the year, programmes on geology, ground-water and soils were brought together in an "Earth Sciences Branch", and work on coal, petroleum, natural gas and gasoline and oil testing in a "Fuels Branch". The ground-water studies are providing basic information on the ground-water resources of Alberta, and have offered substantial annual savings of water costs, for example, from the research on charging of water from Driedmeat Lake into a nearby gravel terrace. In surface geological mapping in the Taber area a buried Indian camp site was uncovered in the valley walls of the Oldman River, and along with Indian artefacts the skeleton of a buffalo and a willow branch were found, for which radiocarbon dating gave an age of 11,000 years. The Geological Division has developed a mineral dressing laboratory with the special purpose of investigating the possibility of refining Alberta sands. Studies of Cretaceous stratigraphy have been expanded into a co-ordinated programme, and a sub-surface study of Lower Cretaceous strata of central Alberta is in progress with the purpose of establishing the interrelations of the marine and non-marine zonations. Upper Cretaceous beds in the Peace River region have been zoned micro-faunally, and the southward marine extension of these strata is being examined for micro- and macro-faunal content.

The Coal Division is continuing an investigation of carbonization, which during the year has shown that the carbonization reaction is much faster than was thought, and the overall reaction is only slow because the coal-tar products have difficulty in working their way out of the carbonaceous residue; the overall reaction can be accelerated considerably in presence of nitric oxide. The Natural Gas Section is examining a process for recovering helium from natural gas, and the Petroleum Division discovered that mud from the bottom of a local lake contained completely developed petroleum pigments along with traces of other oil materials. Pilot plant experiments were extended to work on a concentric flow of heavy oil and water mixtures in a 1,000-ft. experimental pipe-line, which showed that injection of about 30 per cent of water gave a pressure drop of up to about 75 per cent. The Industrial Engineering Services Group has made good progress in studies on carburation to permit the satisfactory use of propene and butane as engine fuels. Studies have been commenced on the effects of various solvents on plastic pipes, and a 500-ft. length of buried pipe carrying natural gas is now being observed under actual operating conditions.

Satisfactory progress is also reported in the highway research programme. The co-operative cloud physics and hail research programme is now in its fourth year, and the results should indicate whether Alberta hail is generally similar to that studied in Europe or whether there are significant differences in structure. The special weather-radar continues to give much information on the cloud systems moving through the area, and a meso-network of some thirty microbarographs has now been arranged at intervals of about 10 miles. Preliminary results from the study of nucleation represent a major advance in the basic approach to the hail problem, and following the study of nucleation commenced last year at McGill University, the work was continued during the summer with the project group at Penhold, where a method of determining the amount of 'freezing nuclei' in rain-water, or water obtained from melted hailstones, was applied.

ROTHAMSTED EXPERIMENTAL STATION

F. C. BAWDEN, whose style of writing could profitably be copied by directors of other research institutes, states in his annual report for 1959 of the Rothamsted Experimental Station* that the ultimate aim of agricultural research must be to increase the efficiency of agriculture by lowering unit costs of production and improving the quality of the produce. The very wide range of activities described in this report offers scope for assessing the contribution of Rothamsted towards this goal. Whether this aim will be better served by the empirical approach of much of the work reported, or by the establishment of general principles formulated on research of a more fundamental nature, is obviously a question which must exercise the mind of any good scientific leader. Perhaps the best compromise is to encourage developments along both lines, the correct allocation of resources depending on many factors.

There is no question that the work on the use of fertilizers, irrigation, and the control of weeds, pests and diseases has the immediate practical aim of increasing agricultural efficiency; but there is plenty of evidence throughout this report of more academic inquiries covering such varied matters as the underground activities of organisms as diverse as slugs, earthworms, fungi, nitrogen-fixing bacteria and an eel-worm that transmits a soil-borne virus; the internal structure of viruses and the relative infectivity of intact virus particles and their separated nucleic acids; the activities of enzymes in insects, bacteria and leaves; the biology of weeds and the relation between the potassium supply of soils and the nature of the clay minerals.

In the Chemistry Department, where work on fertilizers has always loomed large and has been responsible in no small measure for the present high efficiency of arable crop production in Great Britain, much basic work is now proceeding on soil organic matter, nitrogen, phosphorus and potassium. It might fairly be said that soil fertility studies at Rothamsted have suffered in the past from the 'NPK' (nitrogen–phosphorus–potassium) complex; but attention is now being directed towards other elements such as magnesium and molybdenum. Judged by the increasing incidence of hypomagnesemia in farm animals, this interest is timely or even late, and if the work on micronutrients merely indicates that deficiencies of such elements are likely to be rare in Britain, it will serve its purpose.

Biochemistry increasingly emerges as the central discipline in agricultural research; and its impact can be seen in many departments ranging through soil chemistry, botany, pathology, insecticides and fungicides. In the Biochemistry Department itself, work is concentrated on plant enzyme systems, but there is some collaborative work with the Nematology Department on eel-worm hatching factors. One wonders whether the work on the extraction of protein from leaves has not now served its valuable purpose and should be handed over for large-scale development to industry and governments in countries where malnutrition is still a serious problem.

Russian claims that inoculation of soil with *Azotobacter* increases crop yields have been treated with scepticism in the Western world. None too soon, these reports are being properly investigated by the Soil Microbiology Department, and under some conditions, at present ill-defined, inoculation has increased yields significantly.

One of the dangers when a research station reaches the size of Rothamsted is that each department may work on isolated problems when more progress is likely to be made, particularly in biological research, by inter-departmental co-operation. There is disappointingly little evidence of this collaboration where it might be most valuable, for example, between the Chemistry Department, Pedology Department and the Soil Survey of England and Wales. That such co-operation is possible and fruitful is evidenced by the work of the Macaulay Institute in Scotland. On the other hand, it is pleasing to see the Botany Department is studying the effect of soil-water deficit on plant growth, clearly complementing the work in soil physics, where the study of agricultural meteorology, which has already had a notable effect on the practice of irrigation, is being extended into the field of micro-meteorology.

There is an encouraging sign of collaboration in the report of the Entomology Department. Changes in soil fauna brought about by long-term bare-fallowing are being studied, and at the same time other departments will study changes in soil organic matter, microflora, physical properties, organisms causing crop diseases, nematode populations, and the survival of weed seeds. Perhaps this will be the forerunner of other co-operative work, and for a start one might suggest similar studies when land is put down to grass. After all, grass is still the most important crop of Britain, and unless the Agricultural Research Council objects to duplication of effort, it would be stimulating to see Rothamsted paying more attention to grassland soils and some of the problems of herbage production.

CONVERSION OF CYCLOPENTADIENE INTO NEW BICYCLOPENTYL DERIVATIVES

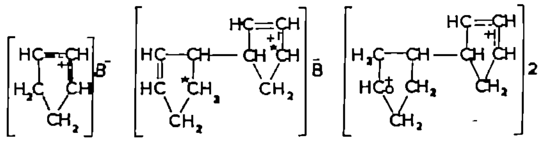
Structure Determination with the Help of Proton Magnetic Resonance Spectroscopy

Diels–Alder diene associations, including the dimerization of cyclopentadiene, are susceptible to trichloroacetic acid catalysis[1], with carbonium ions as intermediates[2]. The catalysed formation of endo-dicyclopentadiene, $C_{10}H_{12}$, was studied at acid concentrations up to 0·16 *M* (25°). It has now been found that at higher acid concentration, for example, 0·5 *M*, cyclopentadiene is almost quantitatively converted into a trichloroacetic acid ester (I). $C_{12}H_{13}O_2Cl_3$, n_D^{25} 1·5085, λ_{max} (ethanol) 242 mμ; ε_{max} 800 l./mol.-cm. This ester polymerizes so quickly on heating that it cannot be distilled, but purification by fractional thawing is possible. Alkaline hydrolysis produces an alcohol (II), $C_{10}H_{14}O$, b.p. 84–86°/0·2 mm., n_D^{25} 1·5105, λ_{max} (ethanol) 243 mμ, ε_{max} 400 l./mol.-cm., 3,5-dinitrobenzoyl ester m.p. 112–113°, phenyl urethane m.p. 64–65°. Bromination and hydrogenation established the presence of two double bonds in ester (I) and alcohol (II); the double bonds must be conjugated because of the specified position of the λ_{max} values.

There is no carbonyl frequency in the infra-red adsorption spectrum of alcohol (II), which excludes the possibility of hydroxyl being attached to unsaturated carbon. Hydrogenation of alcohol (II) produced a saturated alcohol (III), $C_{10}H_{18}O$, b.p. 95°/0·5 mm., n_D^{25} 1·4844, 3,5-dinitrobenzoyl ester m.p. 79–82°, phenyl urethane m.p. 88–92°, acid phthalate m.p. 80–82°, which was dehydrated to hydrocarbons $C_{10}H_{16}$, b.p. 112–115°/100 mm., n_D^{25} 1·4796, the infra-red absorption spectrum of which was very similar to that of a mixture of cyclopentyl–cyclopentenes, prepared according to v. Braun and collaborators[3].

Hydrogenation of both hydrocarbons gave bicyclopentyl $C_{10}H_{18}$, which proves that the alcohols (III) and (II) and ester (I) are bicyclopentyl derivatives. Alcohol (III) was oxidized to a ketone, $C_{10}H_{16}O$, b.p. 74–75°/1·3 mm., n_D^{25} 1·4743, 2,4-dinitrophenylhydrazone m.p. 129–131°, semicarbazone m.p. 197–198°, which was not identical with the well-known 2-cyclopentyl-cyclopentanone. Thus, the hydroxy-group of alcohols (III) or (II) cannot be attached to a carbon atom in juxtaposition to the junction points of the two five-membered rings. The proton magnetic resonance spectrum of pure liquid alcohol (II) is characterized by peaks *A*, *B*, *C* and *D* at − 0·82, − 0·05, 0·18 and 2·72 parts per million (p.p.m.). These chemical shifts (which are defined by the dimensionless number $[H_s - H_r/H_r] \times 10^6$ when H_s and H_r are the resonance fields of sample and reference (water)) are assigned as follows: *A* corresponds to hydrogen on unsaturated carbon, *B* to hydroxyl hydrogen, *C* to hydrogen bound together with hydroxyl to saturated carbon and *D* to the other hydrogens on saturated carbon. The assignment is consistent with the proton magnetic resonance spectra of alcohol (III) and cyclopentanol and with the relative peak positions in the pure liquid state and in carbon tetrachloride solution. Peak area measurements showed that four hydrogens must be attached to unsaturated carbon. An investigation of the proton magnetic resonance spectra of ester (I) and of the trichloroacetic acid esters of alcohol (III), cyclopentanol and ethanol lead to similar conclusions.

All the observations taken together prove that alcohol (II) is 3-(cyclopenta-2′,4′-dienyl)-cyclopentanol.



I I′ I″

The new bicyclopentyl derivatives can be converted thermally and catalytically into polymers of unusual properties, which will be described elsewhere.

Kinetics and Mechanism

The rate, R_{ester}, of the trichloroacetic-catalysed reaction, 2-cyclopentadiene + trichloroacetic acid → trichloroacetic acid ester of 3-(cyclo-2′,4′-dienyl)-cyclopentanol (see previous communication), (ester (I)), has been measured. The results can be summarized by:

$$R_{ester} = k_{ester}[\text{cyclopentadiene}]\,[\text{trichloroacetic acid}]^2 \qquad (1)$$

where k_{ester} is $10^{4\cdot3}\exp(-9900/RT)(\text{l./mole})^2\ \text{sec.}^{-1}$ in carbon tetrachloride and $10^{4\cdot4}\exp(-9700/RT)$ $(\text{l./mole})^2\ \text{sec.}^{-1}$ in benzene. It has been shown before[1] that the rate, R_{dimer}, of the trichloroacetic acid catalysed dimerization, 2 cyclopentadiene → endo-dicyclopentadiene, is given by:

$$R_{dimer} = k_{dimer}[\text{cyclopentadiene}][\text{trichloroacetic acid}] \qquad (2)$$

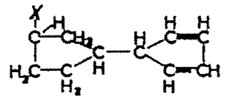
Using k_{ester} and k_{dimer}, relating to 25° and carbon tetrachloride, the ratios R_{dimer}/R_{ester} are 4·4 ± 0·8 and 0 022 ± 0 004 according to whether the trichloroacetic acid concentration is 0·0050 or 1·0 *M*. It is understandable, therefore, why the preparative isolation of ester (I) is only possible if the trichloroacetic acid concentration is sufficiently high (see previous communication).

Rate expression (1), the influence of polar aprotic solvents (nitrobenzene and nitromethane), which increase R_{ester}, and of proton acceptors (water, ethanol, acetone dioxan) which act as retarders, are compatible with a mechanism represented by:

$$M + HB \underset{k'_1}{\overset{k_1}{\rightleftharpoons}} i;\ i + M \underset{k'_2}{\overset{k_2}{\rightleftharpoons}} i';\ i' \underset{k'_3}{\overset{k_3}{\rightleftharpoons}} \text{endo-dicyclopentadiene}$$

$$i' + HB \underset{k'_4}{\overset{k_4}{\rightleftharpoons}} i'';\ i'' \underset{k'_5}{\overset{k_5}{\rightleftharpoons}} \text{ester (I)} + HB$$

In these equations M is cyclopentadiene, HB is trichloroacetic acid, i and i' are singly charged ion pairs $\overset{+}{C}_5H_7 \ldots \bar{B}$ and $\overset{+}{C}_{10}H_{13} \ldots \bar{B}$ and i'' is a doubly charged ion pair $\overset{++}{C}_{10}H_{14} \ldots 2\bar{B}$ (B = trichloroacetate). Application of the stationary state approximation and assuming that $k_1M[HB] \gg k'_1 i'$; $k_2 iM \gg k'_4 i'' + k'_3$ [dimer]; $k_3 \gg k'_2$ or $k_4[HB]$; $k_4 i' \gg k'_5$[ester (I)]; $k_2M \gg k'_1$ leads to (1) with $k_{\text{ester}} = k_1k_4k_5/(k_4' + k_5)k_3$ and to (2) with $k_{\text{dimer}} = k_1$. We suggest the following formulæ for i, i' and i''.



alcohol (II): $X = OH$

ester (I): $X = C_2O_2Cl_3$

Conversion of i' into endo-dicyclopentadiene and of i'' into ester (I) involves removal of one HB; in the former case a C–C bond is formed between the carbon atoms indicated by asterisks, while in the latter case combination of one B^- occurs with the carbon atom indicated by a circle.

It has been shown (unpublished experiments) that the interaction of endo-dicyclopentadiene and trichloroacetic acid leads predominantly to the trichloroacetic acid ester (II′) of exo-hydroxydihydrodicyclopentadiene, rather than to ester (I). Thus the velocity coefficient, k_6, of the reaction endo-dicyclopentadiene + trichloroacetic acid $\xrightarrow{k_6}$ ester (II′) is probably large compared to k'_5.

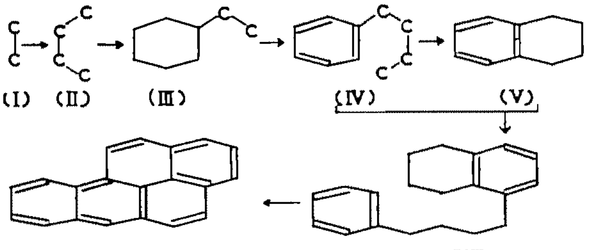
MODE OF FORMATION OF 3,4-BENZOPYRENE IN HUMAN ENVIRONMENT

By PROF. G. M. BADGER, R. W. L. KIMBER and T. M. SPOTSWOOD
University of Adelaide, South Australia

SOOT, coal tar, shale oil and some petroleums have long been recognized as the probable cause of certain 'industrial cancers', particularly cancers of the skin. Yamagiwa and Ichikawa[1] demonstrated experimentally that coal tar has cancer-producing activity in laboratory animals, and a pure carcinogenic hydrocarbon, 3,4-benzopyrene (VII), was isolated from coal-tar pitch in 1933[2]. The same hydrocarbon has since been identified in soot[3] and in shale oil[4]. 3,4-Benzopyrene may be chiefly responsible for the cancers caused by soot, coal tar and shale oil; but other carcinogenic hydrocarbons, notably 3,4 : 8,9-dibenzopyrene, 3,4 : 9,10-dibenzopyrene and 3,4-benzofluoranthene have since been identified in coal tar[5].

In recent years 3,4-benzopyrene and other polycyclic aromatic hydrocarbons have been identified in carbon blacks[6], in processed rubber[7], in atmospheric dust[8], in the exhaust gases of petrol and diesel engines[9], in coal gas[10], in coffee soots[11], in human hair wax[12], in oysters and barnacles taken from polluted water[13], in Icelandic smoked food and in the soot from a smoked sausage factory[14], in snuff[15], in tobacco[16] and in cigarette and tobacco smoke[17]. This widespread occurrence of 3,4-benzopyrene in human environment suggests that this hydrocarbon may be implicated in the causation of some cancers in addition to those of industrial origin. The mode of formation of 3,4-benzopyrene therefore seems to be of importance.

The carcinogenic hydrocarbons which occur in human environment seem to be formed only at high temperatures, that is, by reactions under pyrolytic conditions[18]. Several plausible mechanisms for the formation of 3,4-benzopyrene can be postulated, notably the addition of a two-carbon unit to chrysene or to 1,2-benzanthracene, or of a four-carbon unit to pyrene. As a working hypothesis, however, it was suggested[18] that 3,4-benzopyrene may be formed from simple units by a step-wise synthesis, as in (I) → (VII). Possible intermediate compounds would be ethylene or acetylene (for I), butadiene or vinylacetylene (for II), styrene or ethylbenzene (for III), and phenylbutadiene, *n*-butylbenzene or tetralin (for IV and V).



(I) (II) (III) (IV) (V) (VII) (VI)

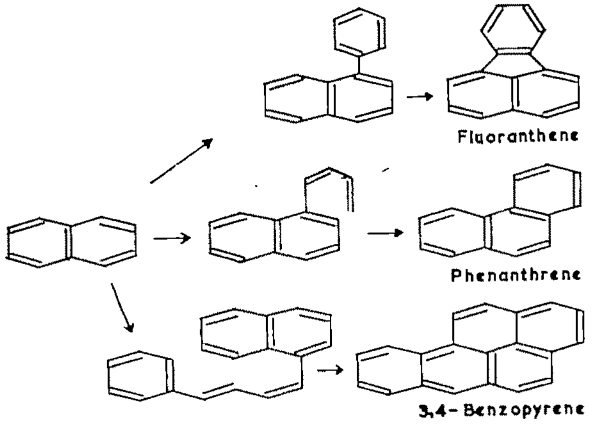
In his classical experiments, Berthelot[19] showed that when acetylene is heated it gives a tar containing benzene and other aromatic hydrocarbons; and Kennaway[20] later showed that tar prepared by passing acetylene and hydrogen through a tube at 700° has powerful cancer-producing properties. It has now been found that tar produced by the pyrolysis of acetylene contains 2 per cent 3,4-benzopyrene[21].

The incomplete combustion of organic compounds often gives some acetylene[22], and acetylene has been detected in tobacco smoke[23]. Nevertheless it seems unnecessary to postulate that the pyrolysis of substances giving benzopyrene invariably proceeds by initial cracking to a two-carbon unit, followed by re-synthesis. Indeed, it seems more reasonable to suppose that the formation of benzopyrene from dicetyl[24] and from aliphatic tobacco hydrocarbons[25], for example, proceeds by initial cracking to a C_{16} unit, which afterwards gives a C_6–C_4 unit (IV, V), and that two such units then give the key intermediate (VI).

The participation of an intermediate such as (VI) in the formation of benzopyrene has some experimental support. When tetralin is treated with aluminium chloride it gives a complex mixture ('Schroeter tar')[26] which becomes carcinogenic on heating[27], and which has now been shown to contain 3,4-benzopyrene[28]. 6-4′-Phenylbutyltetralin is a major constituent of this mixture; some 5-4′-phenylbutyltetralin (VI) would also be expected, and, although none could be isolated[28], its absence may be due to its too ready conversion into the 3,4-benzopyrene actually isolated. Attempts to synthesize 5-4′-phenylbutyltetralin (VI) have so far been unsuccessful; but the related 1-4′-phenylbutylnaphthalene has been shown to give some 3,4-benzopyrene (albeit in small yield) on pyrolysis[29].

In order to test the hypothesis further, several possible intermediate compounds (butadiene[30], styrene[31], ethylbenzene[29], phenylbutadiene[32], *n*-butylbenzene[29] and tetralin[33]), have been pyrolysed at 700° and the resulting tars analysed. 3,4-Benzopyrene has been identified in each case, but the amount formed varied from compound to compound. Moreover, other compounds (toluene[29], *n*-propylbenzene[29] and indene[34]), which are not direct intermediates in the scheme (I) → (VII), were also found to give some benzopyrene on pyrolysis. However, it may be significant that of the simple alkylbenzenes the one having a C_6–C_4 structure (IV), namely, *n*-butylbenzene, gave the greatest quantity of 3,4-benzopyrene[29].

In each case it has been possible to predict which bonds must have the lowest bond dissociation energies, and will therefore be most likely to break (at the high temperature involved) to yield free radicals. The observed products can then be accounted for by secondary reactions involving these initial or primary radicals. In the pyrolysis of phenylbutadiene[32], for example, phenyl-, butadienyl- and phenylbutadienyl-radicals must be important initial radicals; and naphthalene is an important product of this pyrolysis. The presence of fluoranthene, phenanthrene, and of 3,4-benzopyrene in this tar can then be accounted for by attack of the radicals mentioned on naphthalene, followed by cyclodehydrogenation.



In the same way the alkylbenzenes must undergo primary fission to radicals such as $C_6H_5\cdot$, $C_6H_5CH_2\cdot$, $CH_3CH_2\cdot$, etc., and the products can be accounted for by secondary reactions involving these radicals. Chain re-synthesis must proceed to an appreciable extent, for naphthalene is present in all the tars, and this must be formed from a C_6–C_4 unit. The probable mechanism of chain re-synthesis may be illustrated by the following:

$$\begin{aligned} &Ph\cdot + CH_2 = CH_2 && \rightarrow PhCH_2CH_2\cdot \\ &PhCH_2\cdot + CH_2 = CH_2 && \rightarrow PhCH_2CH_2CH_2\cdot \\ &Ph\cdot + CH_2 = CHCH = CH_2 && \rightarrow PhCH_2CH = CHCH_2\cdot \end{aligned}$$

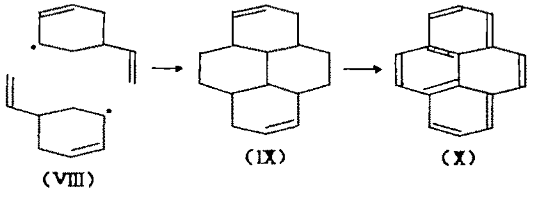
A detailed examination of the results (Table 1) leads to the conclusion that the formation of 3,4-benzopyrene from chrysene or 1,2-benzanthracene by reaction with a C_2 unit can be discounted on the basis of the wide variations in the relative yields of these compounds. The pyrolysis of indene[34], for example, yields little 3,4-benzopyrene, although the yield of chrysene is high and ethylene is present in the exit gases.

Table 1. YIELDS OF 1,2-BENZANTHRACENE, CHRYSENE, PYRENE AND 3,4-BENZOPYRENE IN PYROLYTIC TARS

Hydrocarbon pyrolysed	1,2-Benzanthracene	Chrysene	Pyrene	3,4-Benzopyrene
Acetylene	0·4	0·5	6·5	2
Butadiene	0·31	0·39	1·0	0·34
Toluene	0·014	0·03	det.	0·002
Styrene*	—	c. 2·2	c. 1·9	0·02
Ethylbenzene	0·46	0·55	0·33	0·065
Propylbenzene	0·62	0·96	0·21	0·17
Indene	4·6	31·7	0·10	0·003
Butylbenzene	1·19	1·82	2·0	0·92
Phenylbutadiene	0·89	1·33	—	0·12
Tetralin	2·6	3·43	0·008	0·17

* This analysis was carried out before the development of the technique of chromatography on acetylated paper. The results are therefore not strictly comparable.

On the other hand, it seems that reaction of a C_4 unit (such as butadiene) with a pyrene intermediate may be an important route to 3,4-benzopyrene, in addition to that represented by (I) → (VII). Thus although the pyrene/3,4-benzopyrene ratio is very low for tetralin tar, it is relatively high for most of the other compounds examined. The variation is best explained by assuming that both mechanisms operate to a varying degree depending on the nature of the compound pyrolysed. With the exception of the tetralin tar, in which the benzopyrene may be formed almost exclusively by the route (I) → (VII), it will be noted that tars having high yields of 3,4-benzopyrene also have high yields of pyrene (for example, acetylene, butadiene, *n*-butylbenzene) and tars having low yields of 3,4-benzopyrene have low yields of pyrene (for example, indene).



A suitable pyrene intermediate could be formed as follows. Dimerization of butadiene gives vinylcyclohexene, and two vinylcyclohexene radicals (VIII) could give a hydropyrene (IX). Dehydrogenation of this would give pyrene (X); but addition of another molecule of butadiene followed by dehydrogenation would give 3,4-benzopyrene.

This work has been supported by the Damon Runyon Memorial Fund for Cancer Research Inc., to whom we express our thanks.

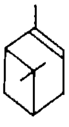
RADIOLYSIS OF TERPENE HYDROCARBONS: ISOMERIZATION AND POLYMERIZATION OF α- AND β-PINENE

By T. H. BATES and DR. T. FFRANCON WILLIAMS

Chemistry Division, Atomic Energy Research Establishment, Harwell

CERTAIN molecular rearrangements characteristic of reactions undergone by mono-terpenoids offer varied examples of processes occurring by carbonium ion mechanisms[1]. In view of recent interest[2-4] in the possibility that reactions induced by ionizing radiation in some organic systems occur in part by ionic species, it seems pertinent to describe some investigations on the radiolysis of α- and β-pinene. All the irradiations have been carried out using cobalt-60 gamma-rays on liquid samples of high purity *in vacuo*.

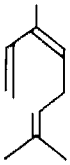
α-Pinene,



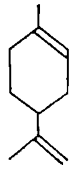
The products of irradiation at the ambient temperature of the source (about 30° C.) consist of hydrogen, isomers of α-pinene, and a low molecular weight ($\overline{M}_n = 428 \pm 9$) polymer corresponding to the average formation of a trimer. Products of molecular weight intermediate between hydrogen and C_{10} compounds are only formed in minute amounts by comparison with the above, as revealed by gas-liquid chromatographic analysis. Yields of hydrogen and polymer, the latter expressed in terms of monomer disappearance, are 0·56 and 5·0 molecules per 100 eV. respectively; the latter yield can only be considered approximate because of the difficulty of removing the last traces of solvent from the polymer.

Isomerization has been studied in detail by gas-liquid chromatography of the irradiated liquid using poly-propylene sebacate as a stationary phase at 90° C.; in this manner it was possible to analyse for concentrations of isomers lower than 0·1 per cent in the α-pinene. The identification of the individual isomers was accomplished by the collection of appropriate fractions on elution from the column and, after further purification, by examination of the infra-red and ultra-violet spectra of the isolated components. By these procedures,

ocimene

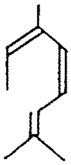


and dipentene



have been identified as the two main isomeric products with initial 100 eV. yields (*G* values) of 2·2 and 0·9 respectively. The rate of growth of ocimene concentration decreases with increasing irradiation dose, and there is evidence of the formation of

allo-ocimene



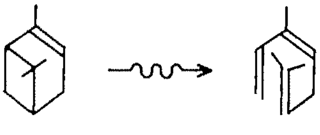
on prolonged irradiation exposure, presumably by further isomerization of the primarily formed ocimene. By contrast, the formation of dipentene is linear with dose up to a concentration of 1·0 per cent in the α-pinene.

Other isomerization or rearrangement products of similar molecular weight are formed in lower yields of which by far the most abundant ($G = 0·6$) is a compound '*X*' with a chromatographic retention time slightly less than that of dipentene, but we have not yet succeeded in identifying its structure; it can be stated, however, that it does not contain terminal group unsaturation (vinyl or vinylidene) and its ultra-violet spectrum does not exhibit evidence of extensive conjugation.

The irradiation of α-pinene at − 196° C. gives *G* values for the formation of ocimene, dipentene and '*X*' equal to 0·8, 1·3 and 0·3 respectively; thus in the solid state the isomerization proceeds more readily to dipentene but is appreciably less facile in favour of ocimene.

It is of related interest that the formation of ocimene, dipentene and allo-ocimene have been observed by Hawkins *et al.*[7] in the vapour phase thermal isomerization of α-pinene using short contact times on an electrically heated element. In the liquid phase it has also been shown[8,9] that the pyrolysis of α-pinene at temperatures exceeding 200° C. leads to the formation of α- and β-pyronenes by the cyclization of allo-ocimene, the latter being itself formed from the initial production of ocimene in the system. By contrast it has been found[10,11] that the homogeneous acid-catalysed isomerization of α-pinene gives mainly monocyclic terpenes, including dipentene, whereas the heterogeneous acid reaction on activated clays gives predominantly camphene; ocimene formation has not been reported under acidic conditions.

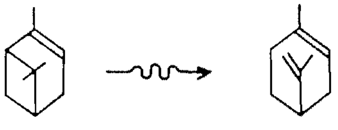
An interpretation of the radiolysis results to allow for ocimene production would be the unimolecular rearrangement of either electronically or vibrationally excited α-pinene molecules by the splitting of the *cyclo*butane ring without the intermediate secession of atomic hydrogen or free radicals; this process can be considered analogous to the mechanism of the thermal decomposition of *cyclo*butane to give two molecules of ethylene[12]. The excited molecules could arise in radiolysis either by direct excitation or by neutralization of the initially created positive ion; it is also feasible that the excited ion undergoes rearrangement to the ocimene structure before neutralization.



(1)

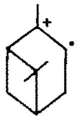
The lower yield of ocimene at − 196° C. relative to room temperature may not be solely due to the increased energy barrier to the isomerization at the lower temperature. Even allowing for the maximum $3n-6$ degrees of vibrational freedom, the energy difference per molecule between − 196° C. and 30° C. would not exceed 1·5 eV., whereas it has been calculated[13] from the Bethe theory that the average energy imparted by fast charged particles to a medium of hydrogen-like atoms is about 5 eV. per direct excitation. A calculation of the activation energy for the first-order thermal decomposition of α-pinene to ocimene and other products from the data given by Hunt and Hawkins[14] gives a value of 37·7 k.cal./mole or 1·6 eV./molecule. It is likely, therefore, that the frequency factor for the rearrangement reaction (1) is adversely affected by the steric confinements of the solid state at low temperature.

The process of dipentene formation is the result of a scission reaction at the gem-dimethyl substituted carbon atom in the *cyclo*butane ring; it can be represented formally as the transfer of a hydrogen atom from one of the methyl groups to the carbon atom at which the *cyclo*butane ring is severed leaving behind an *iso*propenyl group attached at the 4-position in the *cyclo*hexane ring.

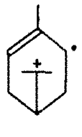


(2)

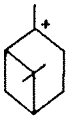
Before proceeding with a more detailed consideration of reaction (2) it is necessary to digress on the nature of the positive ion likely to be formed on irradiation of α-pinene. Chang, Yang and Wagner[5] have suggested that the molecular ion primarily formed on radiolysis of olefin systems is the radical ion produced by localization of the positive charge at the unsaturated carbon atoms; thus for α-pinene it would be represented by I.



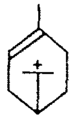
I



II



III



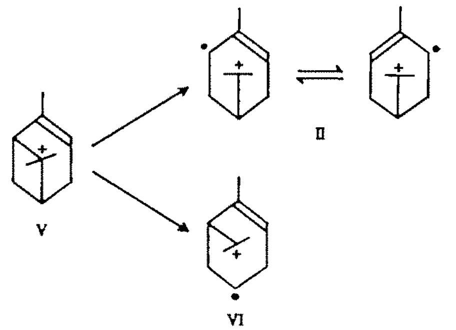
IV

On the basis of the well-understood preferential rearrangement[1] of the carbonium ion III (as produced by proton addition to α-pinene) to the form shown in IV, it can be argued that I would rapidly rearrange to the analogous form shown in II. The mass spectral pattern for α-pinene (A.P.I. Research Project 44, Serial No. 465) reveals that less than 5 per cent of the parent ion is detected, and the most abundant ion is of mass 93, which corresponds to the removal of the $(CH_3)_2C\langle$ group and a hydrogen atom from the parent. However, in the rarefied conditions of a mass spectrometer chamber and because of the relatively large time-interval before detection (10^{-5} sec.), the initial ion is much more prone to extensive decomposition by endothermic step-wise fragmentation than in the liquid phase; in the latter case it is suggested that the more relaxed conditions prevent the further decomposition of the rearranged ion II prior to the eventual neutralization process which has been estimated for some liquid systems to occur in 10^{-12}–10^{-13} sec. (ref. 15). A similar conclusion can be reached as to the likely nature of the positive ion species by comparison with mass spectral findings for alkanes containing quaternary substituted carbon atoms. As an example, the parent ion for neo-pentane is almost non-existent (about 0·01 per cent) in the mass pattern and the main peak is due to the tert-butyl carbonium ion, $C_4H_9^+$. In explanation, Field and Franklin[16] have calculated that the decomposition of the parent ion according to (3) is almost thermoneutral whereas an alternative mode of dissociation given by (4) is 72 k.cal./mole endothermic.

$$\text{neo} - C_5H_{12}^{+} \rightarrow t - C_4H_9^{+} + CH_3^{\cdot} \qquad (3)$$

$$\text{neo} - C_5H_{12}^{+} \rightarrow t - C_4H_9^{\cdot} + CH_3^{+} \qquad (4)$$

An ion dissociation process of type (3) involving negligible activation energy is expected to proceed within a period determined only by the frequency factor of the reaction ; for a simple bond dissociation in an ion, Stevenson[17] has indicated that the frequency factor is 10^{14} sec.$^{-1}$. Accordingly, even in the liquid state, reactions of type (3) may be expected to occur before neutralization, whereas endothermic processes are largely precluded by the short lifetime of the ion (about 10^{-12} sec.). A fuller discussion of the implications of fast ion dissociation reactions for the radiation chemistry of branched hydrocarbon systems, including polymers, will be given by one of us in a future publication[18]. The relevance of a reaction analogous to (3) for α-pinene can be seen by considering the mode of decomposition of the parent ion V ; in this instance it is possible to form two alternative carbonium ions by the scission of the *cyclo*butane ring on either side of the gem-dimethyl group, constituting the quaternary substituted carbon atom in the 'centre' of the molecule, as represented in (5) and (6).

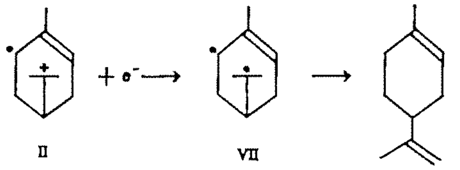


(5)

(6)

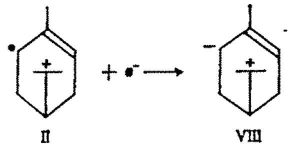
The removal of a methyl group in the above scission is discounted since the largest attached group is generally the most labile in the breakdown of a branched parent ion[18]. Concerning the alternative processes (5) and (6), the former will clearly be favoured by the greater resonance stability of the allylic radical as represented by the equivalent mesomeric structures shown for II. It can therefore be concluded that the most likely ion to be produced in the radiolysis of α-pinene can be represented by II whether the positive charge is initially considered to occur at the double bond or at the tetra-substituted carbon atom ; since these two locations represent regions of high electron density in the original molecule it follows that the positive charge would tend to concentrate preferentially at these locations.

The neutralization of the ion-radical II by the conjugate electron can be represented in three ways : first, by neutralization of the carbonium ion to give a biradical VII followed by disproportionation involving hydrogen atom transfer from one of the methyl groups to the ring position and the concomitant formation of an *iso*propenyl group as represented in (7).



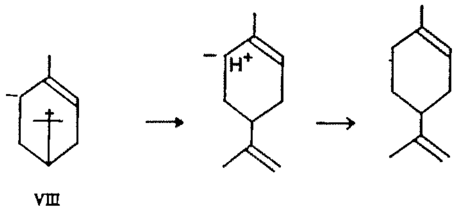
(7)

A criticism of (7) is that the ease of hydrogen atom transfer from the methyl group to the ring position may not be sterically favoured. Secondly, electron capture may proceed at the radical location in II to create an ion-pair VIII in the same molecule, as shown in reaction (8) :



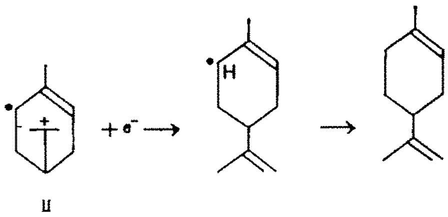
(8)

the postulated relative stability of VIII as an intermediate state is assumed to be derived from the delocalization of the positive charge on the carbonium ion in this instance, accruing from the inductive effect and hyperconjugation of the attached groups. The contribution of solvation forces to the increased stability of tri-substituted carbonium ions may also be of significance[19] although the low dielectric constant of α-pinene is not particularly favourable in this case. Apart from the obvious possibility of ionic combination to re-form α-pinene, there exists the likelihood of proton expulsion from the carbonium ion and concomitant capture of the proton by the negative ion held in close juxtaposition by the coulombic forces of the ion-pair ; these latter processes bear an obvious parallel to the classical S_N1 and *E*1 mechanisms originally invoked by Hughes and Ingold[19] to explain the reactivity of tertiary-butyl halides. So, by analogy, the process of dipentene formation as in (9) can be regarded as equivalent to the elimination reaction found to accompany substitution processes in carbonium ion reactions[20].



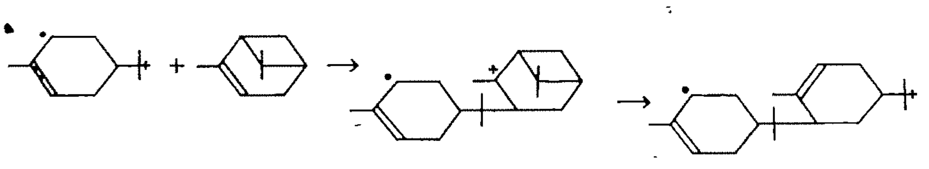
(9)

The third mechanism of neutralization of II is essentially a variant of the previous one in which the electron functions as a nucleophilic entity and attracts a proton from the carbonium ion, thus forming a hydrogen atom. Subsequent combination of the hydrogen atom and the radical would again lead to dipentene as in (10).



(10)

If prior to neutralization the carbonium ion II, or the ion-pair VIII, could transfer its proton to another molecule of α-pinene, then there would be the possibility of the isomerization of several α-pinene molecules per initial ion according to the usual acid-

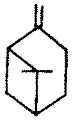


(11)

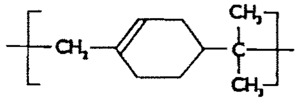
catalysed mechanism[1] of dipentene formation. However, consideration of the yields obtained suggests that the frequency of transfer is small compared with the initial number of ions formed; in this connexion the slight increase in yield at − 196° C. over room temperature conditions may be an indication of some migration in the solid state arising from a longer life-time of II before neutralization. The apparent absence of an isomer of dipentene in the products as would be formed by the alternative mode of scission of the *cyclo*butane ring in reaction (6) is in agreement with the mechanism proposed above.

The negligible yields of methane, ethane and other fragmentation products lead us to argue against extensive radical reactions in this system following from the creation of methyl radicals in a primary act. Polymer formation can be formulated as a consecutive ion-molecule reaction (11) in which the initiating species is the carbonium ion II and the termination process occurs, on average, after the addition of two molecules of α-pinene; the subsequent neutralization of the propagating carbonium ion IX could, by analogy with the isomerization process, give rise to either a diradical, an ion-pair or a radical plus hydrogen atom. If a diradical is formed the molecule could be stabilized by olefin group formation as proposed by Chang, Yang and Wagner[4]. The possibility of proton transfer from a propagating species IX, which thereby terminates, to another α-pinene molecule, thus inducing either a new polymerization chain or isomerization to dipentene, is precluded by the magnitude of the measured yields.

β-*Pinene*,



On irradiation, β-pinene polymerizes readily at ambient room temperature with a large yield, G_{initial} (-monomer) about 2,000, to very high conversions (90 per cent)[11]. If oxygen or water is present the polymerization is inhibited. The polymer was isolated in two fractions according to whether it was insoluble or soluble in the remaining monomer. In a typical experiment, the yield of precipitated polymer was slightly greater than that of the soluble fraction. The insoluble polymer consists of a white solid showing birefringence to polarized light and having a melting point exceeding 200° C., at which temperature it does not undergo obvious decomposition in the absence of oxygen; it is insoluble in most organic solvents of boiling point less than 100° C. Analysis of the carbon and hydrogen content on samples which had either been melted *in vacuo* after irradiation (ostensibly to remove any free radicals formed by irradiation of the precipitated polymer during the polymerization) or been kept in the absence of air gave exact concordance with the formula $(C_{10}H_{16})_n$; however, the analysis of samples further exposed to atmospheric oxygen for more than a week indicated that oxidation had occurred and this was confirmed by infra-red evidence of the formation of $>C=O$ groups on standing. Infra-red examination of the precipitated polymer in a potassium bromide disk immediately after irradiation revealed the spectrum to contain all the absorption bands listed[12] for a sample of β-pinene polymer obtained either by Friedel–Crafts or Ziegler type polymerization, supporting the structural assignment



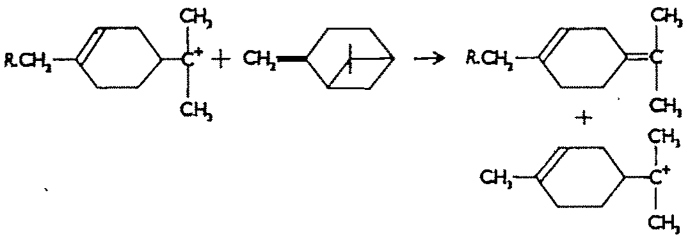
as the most probable repeating unit in the polymer structure. Other absorption bands not characteristic of the Friedel–Crafts polymer and also absent in a sample of commercially available β-pinene resin are found to be consistently present in all polymers formed by irradiation. The soluble polymer was found to have a softening point in the range 80–105° C. and the infra-red spectrum was similar to that of the precipitated fraction; molecular weight measurements by an ebullioscopic method in chloroform as a solvent gave a value of 550. For the total polymer, the molecular weight determinations are uncertain owing to its relative insolubility but a value of 1,450 can be inferred from the data for the portion of sample dissolving in chloroform at its boiling point.

Detailed information as to the polymerization kinetics is not as yet complete; but the results obtained hitherto using pure monomer, prepared by fractional distillation and passage down a silica gel column, suggest that the polymerization is reproducible and not largely affected in terms of yield per total dose either by dose-rate or cell diameter. Irradiation at a mean temperature of −40° C. resulted in a two-fold reduction of polymer yield by comparison with the room temperature results.

By comparison with the ease of the polymerization reaction, the isomerization induced by irradiation of β-pinene is of negligible occurrence and only very low yields ($G < 0{\cdot}1$) of dipentene and other isomers have been observed.

β-Pinene is recognized[13] as typical of a group of monomers that undergo polymerization by ionic initiators such as Friedel-Crafts catalysts but not by free radical agents; for example, the addition of carbon tetrachloride to β-pinene[14] initiated by benzoyl peroxide leads to an almost quantitative yield of 1 : 1 addition product without the formation of polymer, in contrast to the partial polymerization (telomerization) of vinyl monomers in similar circumstances[15].

By complete analogy with the previous discussion for α-pinene, the rearranged positive ion for β-pinene is given by $X =$  ; it is postulated that

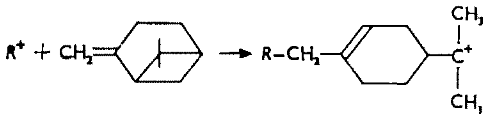


(12)

either this carbonium ion-radical X or the ion-pair

XI =  constitutes the original initiating species for polymerization. The results of this investigation show unequivocally that the high yield of relatively low molecular weight polymer fraction corresponds to the occurrence of a large number (about 100) of separate polymerization chains per 100 eV., and since the number of primarily formed initiators cannot attain such high values the obvious implication is that the polymerization is sustained by transfer of an initiating species from a propagating polymer chain to a monomer. Such transfer mechanisms are well known to occur in ionic polymerizations[26] by proton transfer and are illustrated in this instance by reaction (12).

The propagation step can be written for the general case of the ion R^+ as in (13) and involves the opening of the *cyclo*butane ring as previously conceived for the case of α-pinene.



(13)

For high polymerization yields to be effected by a cationic mechanism in radiation chemistry it is necessary either that the polymerization chain, including possible transfer, occurs in a time of about 10^{-11} sec., that is, before neutralization, or else the conjugate electron must be stabilized for sufficient time to allow the polymerization to proceed in a purely thermal manner before termination. Anderson[4] has suggested the former explanation for the polymerization of butadiene, whereas Dainton[6] and also Davison, Pinner and Worrall[3] have put forward the view that the electron is probably trapped by sub-microscopic solid particles in liquid isobutene. Another general possibility arising from this present work is that of the creation of sufficiently stabilized ion-pair initiators.

According to the mechanism depicted here, the crucial factor governing the magnitude of isomerization and polymerization in these monomers on radiolysis is the ease of transfer of a proton from a carbonium ion to the monomer.

We wish to thank Dr. W. Wild for his interest during the course of this work.

SILKWORM RAISING ON ARTIFICIAL FOOD

By TOSHIFUMI FUKUDA, MITSUMASA SUTO and YOSHIKICHI HIGUCHI

Sericultural Experiment Station, Suginami-ku, Tokyo

ATTEMPTS to rear silkworms, *Bombyx mori*, on an artificial food have been made for a long time. However, there are no reports that silkworm larvæ have been reared on artificial food only from hatching to spinning. Recently, Hamamura[1] and Ito[2] found that silkworms will eat agar-agar containing nutriments for two or three days, and pointed out that this phenomenon is of value for study of food selection of the silkworm larva. Yoshida *et al.*[3] have succeeded in rearing silkworms on artificial food, from hatching to the fourth day of the fifth instar (maximum). They could not, however, get the silkworms to produce cocoons. So we reared silkworms by improving the composition of the artificial food and the method of the silkworm raising devised by Yoshida *et al.*, and succeeded in making silkworm larvæ produce 36 cocoons, starting from 110 worms hatched from eggs. The silkworms pupated, and the fertilized moths laid their eggs.

The composition of the basal artificial diet is given in Table 1.

To this basal diet (8·5 gm.) was added 5 ml. of 20 per cent sucrose solution, and 10 ml. of the inhibitor solution. The inhibitor solution was prepared by

Table 1. COMPOSITION OF THE BASAL DIET

Powdered mulberry leaves*	5 gm.
Potato starch†	1·5 gm.
'Kinako' (a powder of parched soy bean)†	1 gm.
'Koridofu' non-fat (frozen soy bean-curds)‡	1 gm.

* Leaves picked from mulberry trees ('Kokuso' No. 19 and 'Ichinose') were dried at not more than 40° C. under vacuum, and then powdered to pass through an 80-mesh sieve.

† Potato starch and 'Kinako' respectively were passed through an 80-mesh sieve.

‡ The dried 'Koridofu' was treated with ether to remove fat, and then powdered to pass through an 80-mesh sieve.

dissolving 0·1 gm. of vitamin K_3, 0·2 gm. of sodium dehydroacetate and 0·2 gm. of sodium sorbate in 100 ml. of distilled water by heat. This inhibitor is necessary to stabilize the artificial diet, and to prevent its decomposition. The mixture was stirred well with a glass rod. The artificial food prepared was sterilized in an autoclave for 15 min., and stored in a refrigerator. The artificial food thus prepared remains good for a week.

A piece of wet filter paper was placed in the bottom of a Petri dish ready for raising the silkworms. This was covered with a piece of paraffin paper. The artificial food was placed on the paraffin paper, then the newly hatched worms (the hybrids between *Si* 115 × *Si* 124 and *Nichi* 122 × *Nichi* 124) were placed on it and reared there. The dish, covered with a lid, was placed in a sterilized box at a temperature of 25° C. and at 92–96 per cent humidity. The artificial food was cut in slices 0·1 mm.–0·3 mm. thick. Each slice prepared was sterilized in an autoclave for 15 min., and then stored in a refrigerator for 12 hr. before use. Slices were fed to the silkworms twice daily at 12-hr. intervals.

The time between hatching of silkworm larva and spinning a cocoon was 45 days. This is about twice as long as the same race reared on mulberry leaves. The pupal period was 14 days. Fig. 1 shows the silkworms at the eighth day of the fifth instar, three days before spinning, eating the artificial food. Among 110 newly hatched silkworms, 36 spun their cocoons, and 24 silkworms underwent the pupa stage (♀2 and ♂22) and 24 became moths (♀2 and ♂22). The weights of the matured larva, the pupa (at the sixth day after pupation), and the moth were respectively 1·13 gm., 0·62 gm. (♂), and 0·33 gm. (♂). Fig. 2 shows the matured larva, the pupa, the moth, the cocoon, and the eggs obtained by using artificial food. The weight of the cocoon fibres produced by one silkworm was 86 mgm. (130 mgm. maximum), and its value is about 20 per cent (about 40 per cent) of that in the case of the silkworm reared on mulberry leaves. The length of a silk filament unwound from one cocoon was about 450 m. In a matured larva, the pair of silk-glands developed quite well. The number of the eggs laid by one moth was 227. One egg was 1·291 mm. long by 0·952 mm. wide.

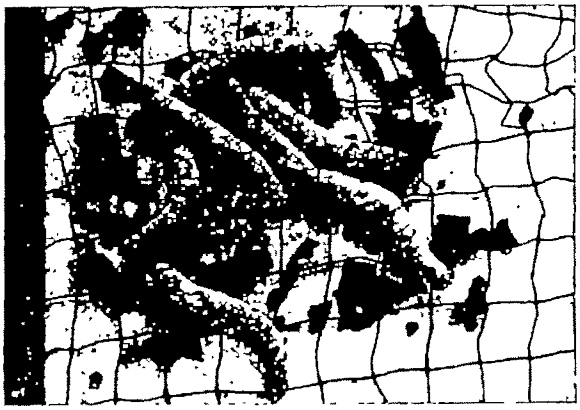

Fig. 1. Silkworms eating artificial food

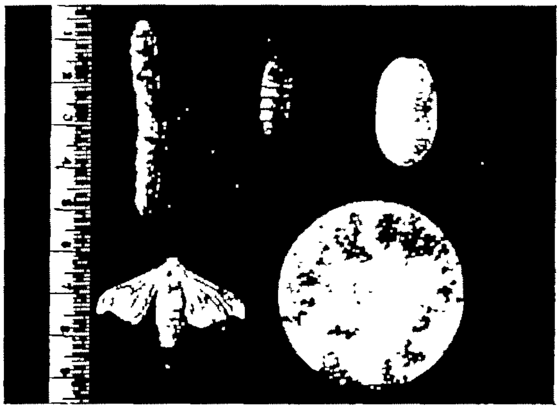

Fig. 2. Mature larva, pupa, moth, cocoon and eggs raised on artificial food

We succeeded in rearing silkworms, from hatching to the moth, on artificial food; but this fact does not mean that the artificial food used is the most suitable one for silkworm raising. The weight of the cocoon fibres obtained at present is not very much. By improving the composition of the artificial food used, however, it may be possible for the silkworm to produce a much larger amount of cocoon fibres and eggs. Concerning the artificial food, especially the powdered mulberry leaves, it is interesting to note that the nutritive value of the powdered leaves decreases remarkably when the powder has been at room temperature for a long time, stored in a glass bottle. In the case of silkworms at the first age reared on an artificial food containing this powder, a great part of the silkworms would not have been raised to the second age. This phenomenon seems to be of interest in relation to the food selection of the silkworm larva. In the artificial food used the powdered mulberry leaves is present in relative abundance (about 20 per cent). It seems to be desirable, if possible, to replace the mulberry leaf powder with some other simple nutriment.

We also tried to rear the wild silkworm (*Attacus ricini*) with artificial food, and succeeded in rearing it until just before the fifth instar, starting from the hatched silkworms. The artificial food used for the wild silkworms was one in which the powdered mulberry leaves were replaced by powdered castor-oil (*Ricinus communis*) leaves, which is used in artificial food for *Bombyx mori*.

We wish to thank Dr. Eikichi Hiratsuka, Dr. Tadao Yokoyama, Dr. Tokutaro Yoshida, Mr. Michio Matsuoka (Sericultural Experiment Station, Tokyo), Dr. Shojiro Ishii (National Institute of the Agricultural Science, Tokyo), Prof. Marcel Florkin (University of Liège, Belgium) and Prof. Jean Leclercq (University of Liège) for their kindness and advice. Our thanks are especially due to Mr. Koichi Kimura for helping us with the preparation of artificial food.

ENZYMATIC ACTIVATION OF A HORMONE-LIKE RESPONSE IN *HYDRA* BY PROTEASES

By Dr. HOWARD M. LENHOFF and JOHN BOVAIRD

Biochemistry Laboratories, Howard Hughes Medical Institute, Miami, Florida

THE mechanism by which excitatory compounds act on cells is not clearly understood. (In view of recent controversy[1], we use the general term 'excitatory compound' as a strictly operational expression to signify any specific substance which functions naturally in eliciting a co-ordinated biological response; thus hormones are the most studied group of excitatory compounds.) Some recent work, which has been concerned with the action of exogenous excitatory compounds on tissue slices[2], is in agreement with the belief that cellular integrity is essential for excitatory compounds to elicit their response[3]. As another approach to this problem, we have been studying the action of an exogenous excitatory compound on an intact, simple, aquatic animal which has not developed past the tissue-level of organization[4]. This system involves the action of reduced glutathione in eliciting the feeding reflex in *Hydra*. In this article we present results which demonstrate that certain proteases can simulate enzymatically the action of reduced glutathione on the live animals.

Small amounts of reduced glutathione have been shown to act as a 'feeding hormone' in eliciting the feeding reflex in *Hydra*[5] and in other hydrozoans[6]. As pointed out by Loomis[5], the feeding reflex involves the well-co-ordinated muscle movements necessary for the ingestion of prey by the *Hydra*. In Nature, the *Hydra* can carry out the feeding reflex only by puncturing the prey with spear-like nematocysts (stinging organoids). After the prey, such as a *Daphnia*, is punctured by the discharged nematocysts, fluids ooze from the wound into the water surrounding the *Hydra*. Reduced glutathione, which is present among these fluids, induces the *Hydra* to carry out the feeding reflex resulting in the ingestion of the wounded prey. Since reduced glutathione is present only in live or recently killed food, the carnivorous *Hydra*, which lacks the specialized sensory organs found in higher forms, is enabled to select living food for ingestion through the stimulation produced by reduced glutathione. Loomis[5] has demonstrated that the experimental addition of reduced glutathione to *Hydra* will induce the animal to ingest even dead food which is devoid of endogenous reduced glutathione.

In the experiments to be described, the feeding reflex is measured quantitatively by averaging the lengths of time (in minutes) during which the mouths of all the *Hydra* tested remained open in response to the protease. This is the procedure by which the normal response to reduced glutathione is measured[4]. Male *Hydra littoralis*, reproducing asexually in laboratory mass cultures[7], were used in all the experiments. The assay consisted of the following procedure: five *Hydra*, which had been starved for one day, were rinsed three times in 30-ml. aliquots of standard culture solution (see below) during a 20-sec. period; then, in one drop of culture solution, they were placed in 2 ml. of the solution to be tested ('test solution'), and were observed immediately through a binocular dissecting microscope. The lengths of time that the mouths of the *Hydra* remained open were recorded, and the average was taken. The test solution was contained in the spherical cavity (38 mm. diameter) of a 3 in. × 2 in. depression slide. The microscope was set at × 19·5 magnification.

The enzymes and proteins used were: papain (twice crystallized), trypsin (twice crystallized), pan-protease preparation, aminotripeptidase, crystalline soybean trypsin inhibitor, peroxidase, collagenase and hyaluronidase (Worthington Biochemical Corp., Freehold, N.J.); chymotrypsin, ficin, pepsin (twice crystallized), cathepsin C, carboxypeptidase, carbonic anhydrase, catalase, α-amylase, and egg albumin (Nutritional Biochemicals Corp., Cleveland, Ohio); urease (twice crystallized), casein and hæmoglobin (Mann Research Laboratories, N.Y.); cellulase, alcohol dehydrogenase (twice crystallized), lactic dehydrogenase, hexokinase and bovine serum albumin (Sigma Chemical Co., St. Louis, Mo.); elastase (Warner-Chilcott, N.Y.); muscle aldolase and α-glycerophosphate dehydrogenase (Southeastern Biochemicals, Inc., Augusta, Ga.), and gelatin (Eastman Chemicals, Rochester, N.Y.). The enzymes and proteins were used at a concentration of 0·1 mgm./ml. unless stated otherwise. All the enzymes were dissolved in the standard culture solution of 10^{-3} *M* calcium chloride and 10^{-4} *M* sodium bicarbonate at *p*H 7·3–7·8, and were dialysed overnight at 4° C. against four litres of this solution. The dialysis was carried out in order to remove any possible contaminating reduced glutathione.

The experiments are listed in Table 1. Experiment 1*a* is a control and shows that in the presence of 10^{-5} *M* reduced glutathione the *Hydra* kept their mouths open for about 21 min.; this was the normal feeding reflex. Results obtained using crystalline papain are given in Experiment 2. The dialysed enzyme (20 μgm./ml.) elicited only a negligible response (Exp. 2*a*). Since reducing agents are known to activate the proteolytic activity of papain[8], the enzyme was incubated with 10^{-3} *M* cysteine for 5 min. A feeding reflex of 20 min. duration resulted (Exp. 2*b*). Cysteine alone, as previously demonstrated by Loomis[5], also was shown here to be without effect (Exp. 1*b*). No response was elicited if the enzyme and cysteine mixture were heated for 5 min. at 100° C. (Exp. 2*c*). (It should be emphasized that the sulphydryl group has recently been shown to be unnecessary for the activity of reduced glutathione on the *Hydra*. These analogues, ophthalmic acid and norophthalmic acid, which have methyl and hydrogen respectively replacing the sulphydryl group of reduced glutathione, can induce the feeding reflex[9]. On the other hand, reduced aspartthione, which contains one less methylene group than reduced glutathione, is inactive[9]. Thus, it appears that the receptor is very specific for the molecular size and shape of reduced glutathione, and does not depend upon the sulphydryl moiety.) Ficin, another proteolytic enzyme activated by cysteine[10], also behaved similarly to papain (Exp. 3). The dialysed ficin did not elicit the response (Exp. 3*a*); addition of cysteine to the enzyme resulted in a significant response (Exp. 3*b*); and boiling destroyed the ability of ficin to elicit the feeding reflex (Exp. 3*c*).

Results obtained using crystalline trypsin are given in Exp. 4. Dialysed trypsin elicited a 17·8-min. response (Exp. 4*a*). The reaction was carried out at *p*H 5·7, which was found to be more favourable for the action of trypsin on the *Hydra*. The action of trypsin in eliciting the feeding reflex was inhibited by previously incubating the enzyme with crystalline soybean trypsin inhibitor (Exp. 4*b*). This action of the trypsin inhibitor was due to the inhibition of trypsin rather than to any deleterious action of the inhibitor on the *Hydra*; for trypsin inhibitor had no effect on the normal response stimulated by reduced glutathione. The activity of trypsin was reduced only slightly by heating at *p*H 5·7 for 5 min. at 100° C. This is in agreement with previous work concerning the relative heat stability of crystalline trypsin at an acid *p*H (ref. 11). However, boiling the enzyme solution at *p*H 7·5 for 5 min., and then adjusting the *p*H to 5·7, reduced the enzymatic activity, and only an 8-min. response occurred.

In summary, the results listed in Table 1 present evidence that the stimulation of the feeding reflex by papain, ficin, or trypsin followed closely the characteristics of the individual enzymes. Papain and ficin acted only in the presence of a reducing agent. Trypsin activity was inhibited by trypsin inhibitor, and was not inhibited by boiling this heat-stable crystalline enzyme at an acid *p*H. It is concluded that the feeding reflex was activated by the proteolytic activities of these enzymes.

In addition to papain, ficin and trypsin, other proteases elicited the feeding reflex in *Hydra*; the pan-protease preparation (*p*H 5·7), 24·5 min.; chymotrypsin, 8 min.; elastase, 1·4 min. Pepsin and cysteine-activated cathepsin *C* were without effect, as were the peptidases carboxypeptidase and aminotripeptidase. Egg albumin was observed on one occasion to elicit a questionable negligible response. None of the 18 other proteins mentioned could elicit a response. The results of this partial survey of proteins suggests that, under the conditions described in this communication, the activation of the feeding reflex is due to the enzymatic action of proteases, and not to any non-specific effect of proteins in general.

Table 1. ACTIVATION OF THE FEEDING REFLEX BY PROTEASES

The experiments were performed as described in the text. The reactions were carried out in the standard culture solution. All solutions were maintained at a near neutral *p*H except for those used in Exp. 4; the latter solutions were adjusted to *p*H 5·7

Experiment	Test solution	Average time mouth of *Hydra* open (min.)
1*a*	10^{-5} *M* reduced glutathione	20·6
b	10^{-5} *M* cysteine	0
2*a*	20 µgm./ml. papain	0·1
b	20 µgm./ml. papain + 10^{-5} *M* cysteine	19·8
c	20 µgm./ml. papain + 10^{-5} *M* cysteine, boiled 5 min. at 100° C.	0
3*a*	0·1 mgm./ml. ficin	0
b	0·1 mgm./ml. ficin + 10^{-5} *M* cysteine	12·3
c	0·1 mgm./ml. ficin + 10^{-5} *M* cysteine, boiled 5 min. at 100° C.	0·1
4*a*	0·1 mgm./ml. trypsin	17·8
b	0·1 mgm./ml. trypsin + 0·1 mgm./ml. trypsin inhibitor	0

The results presented in Table 1 may give the erroneous impression that the opening of the mouth which occurred in the presence of proteases was an abnormal response to a toxic compound. For example, some deleterious compounds have been observed to cause abnormal opening of the mouth, but they did not cause the characteristic feeding response. These poisoned 'gaping' *Hydra* could not carry out the highly co-ordinated movements necessary to ingest dead food (Lenhoff, H. M., unpublished work). In contrast, the *Hydra* reported in the positive enzyme experiments listed in Table 1 (Exp. 2*b*, 3*b* and 4*a*) were able to manipulate and ingest dead food which is devoid of any endogenous reduced glutathione. The ability to ingest food is the most important characteristic of the feeding reflex as determined by Loomis[9]. It should also be noted that the deleterious compounds which cause this gaping usually killed the *Hydra* within a few hours (Lenhoff, H. M., unpublished work). In contrast, the *Hydra* which had been exposed to the proteases for more than 24 hr. in the experiments reported here remained intact and alive.

Preliminary experiments have demonstrated that either trypsin or papain can stimulate isolated *Physalia* gastrozooids to carry out their characteristic feeding reflex (Lenhoff, H. M., unpublished work). Recently these structures have been shown to respond to reduced glutathione in a manner similar to *Hydra*[6].

It seems strange that a response which is so complex and highly co-ordinated as the feeding reflex can be set off by two different classes of substances: the normal excitatory compound—reduced glutathione, and proteolytic enzymes. A consideration of possible mechanisms by which proteases could activate the feeding reflex may give insight into the normal mechanism by which reduced glutathione acts. One possibility may be that the enzymatic cleavage of certain peptide bonds alters the permeability of the cell membrane and triggers the response. Another explanation is that key enzymes, which are needed to initiate the feeding reflex, may be released from their naturally occurring protein inhibitors. For example, proteases are known to activate deoxyribonuclease[12], fructose-1,6-diphosphatase[13], enzymes involved in blood clotting[14] and precursors of proteolytic enzymes[15]. Other enzymes have been shown to exist in combination with heat-labile protein inhibitors[16]. Lastly, co-factors could be released in the same fashion. In the present case, reduced glutathione released from the bound state could be such a co-factor.

As regards the site of action of the proteases, it should be borne in mind that the feeding reflex evoked by the proteases involves many interrelated processes. Most probably these processes could not be initiated by the action of the proteases on any one of the terminal proteins involved in the co-ordinated response. Therefore, it appears that the protease acts on some primary protein which sets off the chain of reactions involved in the complex feeding mechanism. A likely candidate is the reduced glutathione-receptor, or a protein closely associated with the receptor.

Finally, it does not seem inconceivable that the proteolytic activation of a response normally induced by an excitatory compound, such as occurs with *Hydra*, may be found to occur in other systems. The results presented in this communication make it tempting to speculate that a basic underlying mechanism by which some excitatory compounds act on cells involves a proteolytic step.

Note added in proof. After this article was submitted, other examples of systems in which proteases stimulate specific responses came to our attention. Trypsin has been shown to activate wound repair activities of corneal stroma cells; the enzyme was postulated "to lead to the release of some factor(s)" which stimulate these activities[17]. More recently, ficin has been reported to stimulate *in vitro* corticosteroid production by rat adrenal tissue[18]; *in vivo*, adrenocorticotrophic hormone carries out this function.

STRUCTURE AND SYSTEMATIC POSITION OF THE AUSTRALIAN BROWN ALGA, *NOTHEIA ANOMALA*

By M. NIZAMUDDIN
University of Karachi
AND
DR. H. B. S. WOMERSLEY
University of Adelaide

NOTHEIA anomala Harvey and Bailey[1], 1851, was first collected by the United States Exploring Expedition at the Bay of Islands, New Zealand. It grows exclusively on *Hormosira banksii* f. *sieberi* at a low littoral level and in low rock pools on rough coasts, along southern Australia and in New Zealand. Previous studies of *Notheia* have been made by Barton[2], Mitchell[3], Gruber[4] and Williams[5].

The specific name is most applicable to this alga, which has previously always been classed in the Fucales, usually in a family with *Hormosira*. *Notheia* shows a group of three apical cells (which protrude at the branch apex and are not sunk in a depression as in the Fucales), conceptacles scattered over the thallus, and the supposed formation of oogonia with eight eggs, and according to Barton[2], of antheridia with numerous sperms. The branches, which issue from the conceptacles, are a further anomalous feature.

The discovery, while examining living material, that the 'eggs' are motile zooids, made a thorough investigation of *Notheia* necessary. This account gives preliminary results, which, while not complete, clarify many features and show that *Notheia* is not a member of the Fucales but is a distinctive type of the Heterogeneratae. The structure and reproduction will be discussed briefly here and will be described more fully elsewhere.

Each of three protruding apical cells segments latero-posteriorly, and the tissues derived from each apical cell can be recognized in both transverse and longitudinal sections for some distance from the apex, due to extensive mucilage development between the three sectors. Some 15–20 cells from the apex this distinction is lost. Derivatives of the apical cells segment periclinally to form rows of cells which develop three tissues—medulla, cortex and peripheral layer which remains meristematic. The development of the cells is largely filamentous and not parenchymatous; but in older medullary tissue divisions in different planes may occur giving a truly parenchymatous tissue. Increase in thickness of the thallus is largely due to the meristematic peripheral layer, the cells of which divide first by a longitudinal-oblique wall (not reaching the base of the cell), followed by a periclinal division near the base of the larger cell. This results in dichotomous branching, the cells remaining connected by large pit connexions, similar to those of the Florideae. This dichotomous branching is readily visible throughout the cortex in hand sections, but thin microtome sections obscure it.

Branching occurs largely but not entirely from within the conceptacles, resulting in a profusely and irregularly branched plant up to 12 cm. high. The plants originate from within or near the ostioles of conceptacles of *Hormosira* plants. The branches are constricted within and immediately outside the conceptacles, but broaden considerably 1–2 mm. outside; here the cortex is fully developed. Occasionally, however, true branches, up to three per plant, occur; here the thallus divides into two with no decrease in thickness or association with a conceptacle. The common branches may be referred to as 'conceptacular branches' and reasons will be advanced later for suggesting that these are new plants and not real branches.

Conceptacles occur profusely scattered over the thallus. They originate by enlargement and transverse division of a peripheral cell; the upper cell divides to form a hair and the lower divides longitudinally and is overgrown by surrounding cells to form the conceptacle. Most of the lining cells of the conceptacle produce paraphyses which protrude through the ostiole as a dense tuft.

Sessile reproductive organs occur on the wall of the conceptacles. Most common are those containing 8 zooids, while slightly smaller ones with 64 zooids vary from plentiful to absent in some conceptacles. The larger organs measure 48–78μ by 12–30μ and are not oogonia but are macrozoosporangia, liberating 8 pyriform macrozoospores through basal, or occasionally lateral or terminal, pores. The macrozoospores are first extruded in a gelatinous envelope, and when they escape are sluggishly motile by means of a long anterior flagellum and somewhat shorter posterior one, the attachment being lateral but close to the pointed apex. Macrozoospores contain 2–4 chromatophores, a single eye-spot and measure 12–27μ × 5–12μ.

The 64 zooids, formed in organs slightly smaller than the macrozoosporangia, are actively motile, almost colourless (with one pale chromatophore), with an eye-spot and two unequal flagella attached near the apex. They measure 6–10μ by 4–6μ. These bodies settle after one-half to several hours but have never been observed to develop further and their nature is still unknown.

During repeated observations no fusion between the large and small zooids has been observed, although they were moving close together.

The macrozoospores germinate in culture into branched, filamentous gametophytes, with erect colourless hairs. The cells of the prostrate parts measure about 12μ in thickness, are 2–4 times as long as broad and contain several brown chromatophores. Uniseriate, erect reproductive bodies are produced on older filaments, each cell producing a single zooid which is liberated apically through the series of fertile cells. These zooids are pyriform, about 8μ × 6μ and biflagellate with lateral, unequal flagella, similar to the macrozoospores. These gametophytes and reproductive cells are very similar to the gametophytes and uniseriate gametangia of *Spermatochnus paradoxus*[6].

Branched, filamentous growths such as those found in culture occur frequently within the conceptacles of *Notheia*, as was observed by Barton[2]. These filamentous growths are usually entirely within the conceptacle, ramifying among the paraphyses and lining cells, but with their colourless hairs sometimes protruding from the ostiole. Occasional empty uniseriate reproductive cells have been seen on them.

Satisfactory chromosome counts have not yet been obtained, but some 26–30 chromosomes have been observed in vegetative cells, about 20–24 in paraphyses and 12–15 in later divisions in the macrozoosporangium. The thallus of *Notheia* is probably diploid, and the macrozoospores and macrogametophyte haploid.

Until the nature of the microzooids and the zooids from the uniseriate gametophytic reproductive organs is known the full life-cycle of *Notheia* will remain uncertain. It seems likely that the macrogametophytes bear uniseriate gametangia producing a single gamete per cell. The behaviour of the microzooids towards these gametes has not yet been observed.

From the known facts, it appears likely that the macrozoospores germinate into macrogametophytes largely within the conceptacles, and possibly fertilization also occurs within the conceptacles, giving rise to a zygote which grows from the wall of the conceptacle. If macrogametophytes develop outside the conceptacles and fertilization occurs externally, the zygote probably is unable to develop without being associated with *Notheia* or *Hormosira*.

This speculation agrees with the development of new conceptacular branches. Commonly one, sometimes two or three, branches emerge from a conceptacle, and young stages have been observed by us and by previous authors[3,4] growing from the lining wall cells of the conceptacle. This would mean that the gametophytic stage of *Notheia* is entirely endophytic within the conceptacles, and that *Notheia* is essentially a simple or occasionally truly branched plant; the normal *Notheia* plant is actually a compound plant consisting of numerous individuals of possibly several successive generations. Occasional establishment of new *Notheia* plants from *Hormosira* conceptacles might occur by macrozoospores escaping from *Notheia* conceptacles and developing near or inside adjacent *Hormosira* conceptacles, with subsequent fertilization (?) and development of the zygote within the *Hormosira*. The one record of *Notheia* on *Xiphophora* may be a rare chance occurrence.

Notheia is clearly to be classed in the Heterogenerataе group of the brown algae, having different sporophytic and gametophytic generations. The development of the thallus is essentially filamentous, but probably with some true parenchymatous cell formation at older stages. It shows some relationship with certain members of the Chordariales, such as *Spermatochnus paradoxus*[6], which has somewhat similar apical cells and gametophyte, but the only member of this group showing conceptacle formation is the southern hemisphere *Splachnidium rugosum* (which has only one type of sporangium with numerous spores).

Notheia differs from all Chordariales, and in fact from all brown algae, in forming two types of zoospores (if the microzooids are in fact zoospores). Other distinctive features are the three apical cells, the cortex of dichotomous chains of cells with prominent pit connexions, the conceptacles and the endophytic gametophytes and development of new branches. The systematic position of *Notheia* must await knowledge of the full life-history but it certainly forms a distinctive family (Notheiaceae Kuckuck *ex* Schmidt), which may come within the Chordariales or may justify an order of its own.

Brown algae forming zoosporangia normally produce numerous zoospores. The reduction to eight macrozoospores is noteworthy, as well as the production of two morphologically distinct zoospores. *Notheia* may well indicate the possible origin of the Fucales, since were the macro- and micro-zooids to function as gametes (gametophytes being eliminated) and the apical cells become sunk in a depression, the resultant alga would undoubtedly agree well with the Fucales. It is quite possible that the microgametophyte has been eliminated already, and the microzooids function as male gametes; this, however, is still speculation and awaits further examination.

LETTERS TO THE EDITORS

ASTRONOMY

Light Curves of Meteors

THE luminosity equation for the trail of a meteor is[1]:

$$I = \tfrac{1}{2}\left(\frac{dm}{dt}\right) v^2 \tau \qquad (1)$$

where I is the luminous intensity at any point of the trail, $\left(\frac{dm}{dt}\right)$ is the rate of ablation of the meteoroid at that point, v is the velocity of the meteoroid, and τ is the luminous efficiency factor which determines what fraction of the kinetic energy of the ablated atoms is converted into visible light radiation. It is generally assumed that for bright photographic meteors $\tau = \tau_0 v$, where τ_0 is a constant[1,2]. The luminosity equation therefore becomes:

$$I = \tfrac{1}{2}\left(\frac{dm}{dt}\right) v^3 . \tau_0 \qquad (2)$$

This means that the maximum luminosity of the trail will correspond to the level of maximum rate of ablation of the meteoroid.

In a recent paper, Hawkins and Southworth[3] have pointed out on the basis of their study of a random sample of 360 meteor trails photographed with the Baker Super Schmidt cameras at New Mexico that the observed lengths of the trails are considerably shorter than that predicted by the theory. In one of a series of papers on "The Physical Theory of Meteors", Cook[4] had directed attention to the fact that the early portion of a bright meteor trail studied by him was fainter than predicted by the conventional theory. He worked out an improved theory on the reaction zone model taking into account the thermal radiation from the meteoroid, and found that the modified theory provided a completely satisfactory fit to the observed light curve. Öpik[5] has, however, taken exception to the procedure adopted by Cook, and has stated that there is no physical justification for it. In another paper of the series on "The Physical Theory of Meteors", Jacchia[6] has emphasized several anomalies shown by the light curves of faint meteors and has suggested that the theory of progressive fragmentation of the meteoroid along its trail affords a satisfactory explanation of these anomalies.

On the basis of the single-body theory and assuming that $\tau = \tau_0 v$, it can be shown that the equation for the light curve of a meteor is:

$$I = K_1(1 - x)^2 x \qquad (3)$$

where K_1 is a constant for an individual meteor, and $x = \frac{p}{p_e} = e^{-h/a}$, where p is the atmospheric pressure at the level corresponding to luminous intensity I, p_e is the pressure at the level corresponding to the end of the trail, h is the height interval between p and p_e and a is the mean scale height of the atmosphere at the levels appropriate to the meteor trail. This equation indicates that, irrespective of the original mass of the meteoroid, the level of maximum luminosity will be at a height of $a \log_e 3$ ($\sim 1{\cdot}1a$) above the level of complete ablation, and that the equivalent radius and mass of the meteoroid at the level of maximum luminosity will be 2/3 of its original radius and 8/27 of its original mass, respectively[1,2].

The equation for the light curve can be normalized by expressing the luminous intensity at any point of the trail in terms of the maximum luminous intensity. The corresponding equation expressed as magnitude difference is:

$$M - M_{\text{max.}} = \Delta M = -2{\cdot}5\left[2\log(1 - x) + \log x + \log\left(\frac{27}{4}\right)\right] \qquad (4)$$

Assuming a scale height value of $a = 6{\cdot}38$ km. the relation between ΔM and h is represented graphically by curve 1 of Fig. 1. This is identical with the theoretical curve in Fig. 5 of the paper of Hawkins and Southworth[3]. Following their procedure, the points corresponding to the beginning and end of the meteor trails have been plotted in Fig. 1 against the appropriate ΔM values. Almost all the points lie within the theoretical curve, showing that the actual lengths of meteor trails are appreciably shorter than what the theory indicates.

I have modified the conventional theory by assuming that τ is not a constant but varies along the trail of an individual meteor, being proportional to the density of the environment at every point of the trail. In this case the equations for I and ΔM become:

$$I = K_2(1 - x)^2 x^2 \qquad (5)$$

$$M - M_{\text{max.}} = \Delta M = -2{\cdot}5[2\log(1 - x) + 2\log x + \log 16] \qquad (6)$$

where K_2 is a constant for an individual meteor and the other symbols have the same meaning as before.

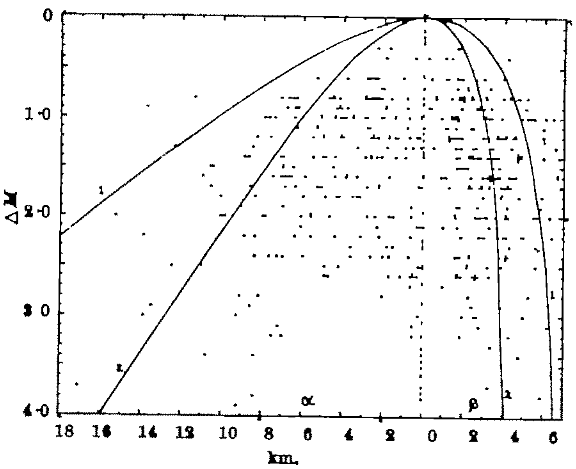

Fig. 1

It can be easily shown that the level of maximum luminosity—this is now different from the level of maximum rate of ablation which remains the same as before—is now at a height of $a \log_e 2 (\sim 0 \cdot 7a)$ above the end of the trail, and that the equivalent radius and mass of the meteoroid at this level will be half its original radius and 1/8 of its original mass, respectively. The relation between ΔM and h is now represented by curve 2 of Fig. 1, which gives a shorter trail for the meteor and the descending branch of which is nearly the median curve through the cluster of points corresponding to the ends of the meteor trails. It will be seen that the modified theory shows better agreement with observation, thus indicating that the interaction between the ablated meteor atoms and the air molecules, which is the primary cause of light emission, has to be explicitly taken into account in the luminosity equation.

The modified theory accounts satisfactorily for the observed light curve of the meteor trail studied by Cook[4]. This meteor appeared at a height of 114 km. at $M = +1 \cdot 9$; it attained maximum luminosity at a height of 84 km. at $M_{\text{max.}} = -5 \cdot 7$; it disappeared at a height of 78 km. at $M = -2 \cdot 6$. For the ascending part of the light curve we have, therefore, $\Delta M = 7 \cdot 6$ and $h_b - h_m = \alpha = 30$ km.; for the descending part $\Delta M = 3 \cdot 1$ and $h_m - h_e = \beta = 6$ km. The values of α and β according to the conventional and modified light curves for certain values of scale height are given in Table 1.

Table 1

		α				β		
a (km.)	ΔM	Conventional theory (km.)	Modified theory (km.)	Observed (km.)	ΔM	Conventional theory (km.)	Modified theory (km)	Observed (km.)
6 38	7·6	50·2	27 2	30 0	3·1	6·4	3 9	6 0
7·00		55·8	30 2			7 1	4 3	
8 00		62 8	34 0			8 0	4·9	

The scale height values considered here are of the correct order as given by the Rocket Panel[7]. We see that the agreement between the modified theory and observation is satisfactory while the conventional theory gives too high values for the length of the meteor trail.

It can be shown that the large scatter of the points corresponding to the beginning of the meteor trails in Fig. 1 and the comparatively smaller scatter of the points corresponding to the end of the trails lend support to Jacchia's fragmentation theory as the cause of meteor anomalies. Fuller details will be published elsewhere.

GEOPHYSICS

Longitude Effect in Temperate Zone Sporadic E and the Earth's Magnetic Field

A RECENT study[1] of the occurrence of sporadic E has shown that the percentage of the time $f_0E_s >$ 5 Mc./s. exhibits a marked longitude effect, having a maximum ($\sim$ 30 per cent) over south-east Asia and minima over South Africa ($\sim$ 3 per cent) and the north-east part of the United States ($\sim$ 6 per cent). That the effect is real, and not due to differences of equipment sensitivity, has been confirmed by very high-frequency forward scatter experiments over the Caribbean and the Philippines[2]. The suggestion was put forward that this longitude effect may depend in a complex manner on both geographical and magnetic latitudes or may be due to meteorological effects[3].

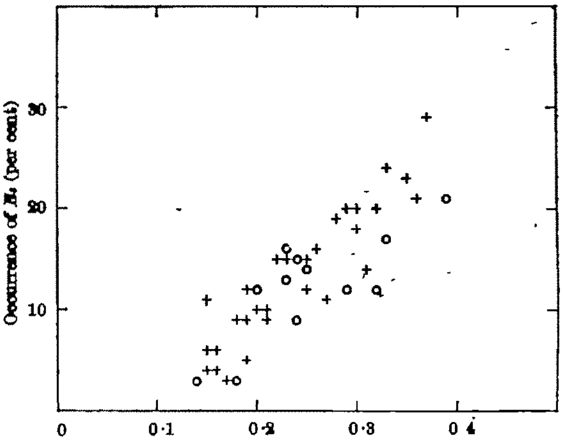

Fig. 1. Plot of percentage of time $f_0E_s > 5$ Mc./s. against horizontal component of the Earth's magnetic field. +, Northern hemisphere; O, southern hemisphere

The purpose of this communication is to point out that the horizontal component of the Earth's magnetic field has a similar variation at the Earth's surface. In Fig. 1 the percentage of the time $f_0E_s > 5$ Mc./s. for the thirty-one ionosonde stations mentioned by Smith[1] is plotted against the magnitude of the

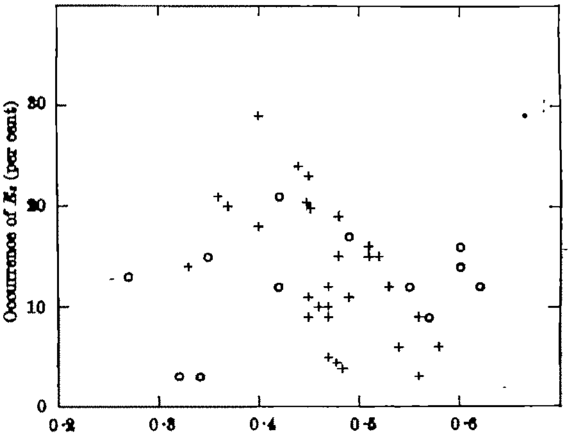

Fig. 2. Plot of percentage of time $f_0E_s > 5$ Mc./s. against total intensity of the Earth's magnetic field. +, Northern hemisphere; O, southern hemisphere

horizontal component. Results from both northern and southern hemispheres follow the same pattern.

That it is the horizontal component which is correlated with sporadic *E* appearances is confirmed by plotting the percentage time $f_oE_s > 5$ Mc./s. against the total intensity of the Earth's field (Fig. 2). There is no correlation between the two. There is some correlation between the occurrence of sporadic *E* and magnetic dip though this is almost entirely due to their correlation with the horizontal component.

It is of interest to inquire which of the various theories put forward to account for sporadic *E* depend only on the horizontal component of the Earth's magnetic field. Ionization by neutral particles or meteors does not depend on magnetic field at all but ionization by charged particles may be confined to a narrow region in the presence of a magnetic field. The total intensity, however, seems to be of importance here. Movement of existing ionization by winds or electric fields seems to be the most likely source of sporadic *E*, and is being studied further.

Geomagnetic Noise at 230 kc./s.

GEOMAGNETIC radio noise or 'hiss' usually occurs only in the audio region. During severe magnetic storms it has been reported up to 30 kc./s. on a sweep frequency analyser[1] and at 70 and 180 kc./s. on fixed tuned channels[2]. The latter report[2] was written after the records had been destroyed in a fire. New observations at up to 230 kc./s. are described here.

Observations were made simultaneously at the four frequencies 4, 9, 70 and 230 kc./s. (using two dual-beam cathode-ray oscillographs and photographic recording) over the period mid-September to mid-November, 1959. Geomagnetic noise was observed on three occasions only: 2245 U.T., October 31; 0430 U.T., November 3; and around 0330 U.T., November 6. The planetary magnetic index (k_p) ranged from 4 to 6 at these times. The noise burst observed on November 6 is reproduced in Fig. 1. This shows 9 and 230 kc./s. only, since the camera recording 4 and 70 kc./s. jammed on this occasion.

The general appearance of the noise burst—relatively gradual rise and decline of intensity (as distinct from the sharp 'on' and 'off' of man-made interference) and impulsive noise component superimposed on a steady or 'white' noise-level—is typical of geomagnetic noise bursts observed at audio-frequencies. The maximum noise-levels are seen to be 0·8 μV.m.$^{-1}$ (c./s.)$^{-\frac{1}{2}}$ at 9 kc./s. and 16 mμV.m.$^{-1}$ (c./s.)$^{-\frac{1}{2}}$ at 230 kc./s., corresponding to intensities of about 10^{-15} W.m.$^{-2}$ (c./s.)$^{-1}$ at 9 kc./s. and 3×10^{-19} W.m.$^{-2}$ (c./s.)$^{-1}$ at 230 kc./s. The intensities observed at 4 and 9 kc./s. at these times were typical of strong bursts at these frequencies. The 70 and 230 kc./s. intensities were of the same order as previously reported[2]. A striking feature of Fig. 1 is the close correspondence of amplitude fluctuations at the two frequencies. These appear simultaneous to the limit of reading of the time scale ($\sim$ 10 sec.).

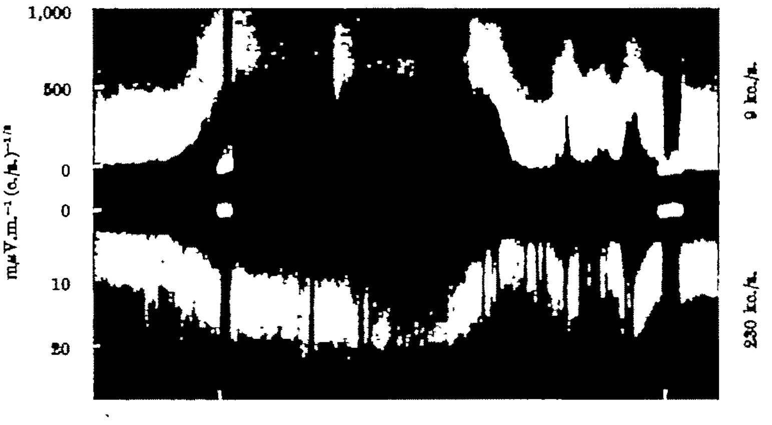

Fig. 1

A probable mechanism for generation of this noise is Čerenkov radiation from small clouds of charged particles travelling through the ionosphere and exosphere[1,2,3]. Radiation is produced at all frequencies for which the velocity of the particle clouds exceeds the group velocity of the radiation (Čerenkov condition). The close correspondence between the two frequency components observed suggests production by the same particle clouds and in the same geomagnetic tube of force since moving charged particles are effectively constrained to a tube of force.

Accordingly the tube of force ending at Hobart (geomagnetic lat. 52° S.) was considered, and the group velocities of 9 and 230 kc./s. radiation calculated[4] as a function of distance along this tube of force. Electron density as a function of radial distance was obtained from whistler data[5]. The assumption was made that the electron density in the exosphere is spherically distributed. At 9 kc./s. it was found that the group velocity would be everywhere less than 0·12 c. from the ionosphere to the equatorial plane (total distance 15,000 km.). At 230 kc./s. only radiation produced below the gyro-level is observable on the ground. From the ionosphere to the gyro-level (a distance of about 5,000 km.) the 230 kc./s. group velocity would be everywhere less than 0·17 c. Consequently, particle clouds travelling down this tube of force at 0·2 c. (say) could produce Čerenkov radiation at both frequencies. Since the travel-time even of 9 kc./s. radiation produced at 15,000 km. would be less than a second, bursts of radiation at the two frequencies would arrive at the ground simultaneously to our limit of reading.

Estimates of absolute intensities to be expected from the Čerenkov process depend too strongly on unknown factors (for example, size and number of clouds and cloud density) to be meaningful. But we can make an order-of-magnitude estimate of the relative intensities based on reasonable assumptions. If these unknown factors were the same for both frequencies we would find that the ratio of intensities produced at 9 and 230 kc./s. would be proportional to the path-length in wave-lengths for which the Čerenkov condition holds[3]. This indicates that the intensity produced at 230 kc./s. should be nearly ten times that at 9 kc./s. However, this ratio will be modified by the ear trumpet effect of the converging tube, giving enhancement proportional to the tube cross-section, which is in turn inversely proportional to the field-strength or gyro-frequency. For the tube of force under consideration this will enhance the ratio in favour of 9 kc./s. by a factor of five. Also if the attenuation in regions of high collision frequency is taken into account (from Helliwell's curves[4]) we find that 230 kc./s. will be attenuated by about eight times as many decibels as 9 kc./s. Agreement with the ratio of intensities observed at Hobart (3×10^3 or 35 db.) is reached for an assumption of about 5 db. for 9 kc./s. and hence about 40 db. for 230 kc./s.

Consideration of tubes of force ending farther south of Hobart require attenuations of 9 kc./s. considerably less than this, in keeping with observations of multi-echo whistler trains. Thus estimates based on this mechanism give reasonable agreement with observations of wide-band noise bursts for frequencies from a few kc./s. to a few hundred kc./s.

It is interesting to note that for this mechanism wide-band bursts will only be observed if the electron density distribution along a line of force is such that the plasma frequency is always greater than the gyro frequency for the range of frequencies observed. Since the electron density in the equatorial plane is obtained from whistler data this gives a lower limit to electron density at each point along the line of force.

My thanks are due to Mr. G. T. Goldstone, who built much of the equipment and assisted in the observations, and to Mr. P. S. Bowling who provided housing for the equipment in the field.

GEOLOGY

The American Oligocene

EAMES *et al.*[1] claim that the Oligocene is not represented in the marine sediments of the western hemisphere. This claim seems to conflict with the palæogeographic status of the region.

The Eastern Venezuela Basin may be taken as representative. In Trinidad the Lizard Springs, Navet, Cipero and Lengua formations form a continuous sequence of Palæocene to Miocene age. They are deep-sea deposits, essentially *Globigerina*-oozes, which accumulated along the axis of the basin.

If any appreciable time-interval is not represented in this sequence, its absence must be explained in one of three ways, namely: (1) sedimentation ceased temporarily; (2) sediments were deposited but were eroded subaerially; or (3) sediments were deposited but were removed by subaqueous processes.

Cessation of deep marine sedimentation scarcely merits consideration. The joint accumulation of fine terrigenous material and foraminiferal tests continues in basinal deeps regardless of orogenic and epeirogenic modifications of the peripheral land areas.

A pre-requisite for subaerial erosion would be uplift and emergence of the sea-floor. If this had occurred there would be abundant evidence of orogeny and regional unconformity. Even if the uplift had been epeirogenic, leaving few physical signs of unconformity, the subsidence which followed would leave the unmistakable evidence of shallow marine beds grading up into deep marine marls. The only such interruption of the deep marine sequence in Trinidad is the San Fernando formation, which is firmly correlated with the Upper Eocene (Jacksonian stage) of the region. The upper beds transitional from the shallow marine San Fernando formation to the deep marine Cipero formation are post-Eocene (*G. ampliapertura* zone).

(Eames *et al.* consider the rich Eocene faunas of the San Fernando formation re-worked in the basal Miocene. In more regional terms they imply that the "Jacksonian transgression" was an early Miocene event. The only reason given is their belief that the genus *Pliolepidina* is a Miocene index. It deserves note that in the Eastern Venezuela Basin there are extensive algal-orbitoidal reef limestones which contain *Pliolepidina* in association with such Eocene indices as *Tubulostium*, *Echinolampas*, *Oligopygus* and *Asterocyclina*. These are purely organic limestones with no clastic content except the finest of silt. The *Pliolepidinas* are definitely not re-worked, therefore this genus is unacceptable as a Miocene index in this region.)

Large-scale slumping is recognized throughout the sedimentary column in Trinidad. It is feasible, and even probable, that at any given locality some part or other of the sequence is missing by reason of submarine slumping, but it is scarcely feasible that one particular interval should be missing in this matter over the whole area. Even if this odd situation did exist on the basinal flanks the displaced beds would presumably be recognized in an allochthonous position towards the axis, and their true stratigraphic status would be established by faunal study.

In more regional terms the sequence of Upper Eocene overlain by the *G. ampliapertura* zone is known in a variety of facies ranging from shallow to deep marine. In all cases the same uniform change in the planktonic fauna defines the contact. This implies that, if there is a major hiatus between the two units, it is no more pronounced around the old land masses than in the basinal deeps, a conclusion contrary to the normal precepts of palæogeography. The Eocene top usually falls within a lithologically uniform sequence. Faunally the contact is mainly defined by extinction of a few Eocene species, not by a wholesale change of fauna. No fauna has been recorded which might fit between the suites of the Upper Eocene and the *G. ampliapertura* zone, themselves closely interconnected by evolutionary bonds. It is not realistic to postulate extensive re-working of the Eocene faunas, which are homogeneous except for an appreciable facies-variation consistent with basinal position. This latter remark applies to Trinidad, where the Upper Eocene faunas are certainly not re-worked in the ordinary usage of that word, though the type San Fernando formation might prove to be an enormous slumped mass. I have studied this interval in Ecuador, Colombia, Venezuela, Trinidad and Barbados in the New World, as well as in Egypt and France in the Old World, and have seen no significant variation from the pattern described. Published records confirm that the same is true in other countries. The one exceptional case is in Antigua, where the *G. ampliapertura* zone rests unconformably on volcanic rocks. The natural conclusion to be drawn is that sedimentation was regionally continuous from the Eocene into the *G. ampliapertura* zone, in which case the latter must be Oligocene.

This palæogeographic reasoning makes regional absence of the Oligocene unlikely in the marine sediments of the western hemisphere. Therefore an alternative explanation would be preferred for any palæontological argument which seems to point to that conclusion. In particular, Eames *et al.* note a new suite of planktonic foraminifera in the Oligocene of East Africa and infer absence of the Oligocene in America because this suite is not known there. An alternative inference is that the new fauna reflects climatic segregation of planktonic suites. Preference of certain species for certain latitudes is well established among the Recent planktonic foraminifera. The marine mid-Tertiaries in the region encompassed by Ecuador, the Gulf Coast States and Trinidad are readily correlated by the planktonic zonation of Bolli (1957) and earlier workers, but both south and north of this tropical belt the scheme tends to break down because the marker-species are scarce or absent. Likewise in the Mediterranean region almost the same zones are recognizable, but attempts to apply the zonation in northern Europe have failed because a different, boreal suite of plankton is present. It seems that a similar situation might well exist in the southern parts of Africa and South America. The observed affinities of this new fauna to Oligocene plankton in Germany and Russia, but apparently not in the Mediterranean countries, give some support to the concept of distinct tropical–subtropical and boreal–austral suites of planktonic foraminifera in the Oligocene.

No detailed comments are offered here on the status of larger foraminifera in this problem, but I opine strongly that the palæogeographical evidence for the presence of the Oligocene in America should outweigh strictly faunal evidence pointing to the contrary. The case of *Pliolepidina*, already cited, shows that like forms were not precisely coeval over the entire world. Regarding the Miogypsinidae, doubt is expressed as to their presence in the *G. ampliapertura* zone as I have never encountered them *in situ* below the *G. dissimilis* zone. Kugler (1954) has referred to them in the older zone, but specifies that he is writing of allochthonous material slumped into Miocene marls. The presence of the ancestral *Rotalia mexicana*-group in the *G. ampliapertura* zone in Ecuador, Colombia, Mexico and Puerto Rico makes the presence of Miogypsinidae at that level improbable.

Extensive bibliographical references to these matters are included in a paper about to be published[2].

[1] Eames, F. E., *et al.*, *Nature*, 185, 447 (1960)

[2] Stainforth, R. M., *Rev. Micropaléont.* (in the press).

Following from Dr. R. M. Stainforth's comments on our communication, we would direct attention to the fact that it contained merely some of the conclusions reached in our study of "Mid-Tertiary Stratigraphical Palæontology", which will be published as an entire, illustrated book, and it is obvious that we could not give the full background in such a short space. However, the following is a very brief outline of part of the picture which has emerged from our studies.

The standard European stages of Upper Eocene, Oligocene and Lower Miocene ages may be traced from the European molluscan facies into the Mediterranean region, where they can be defined in terms of planktonic and benthonic foraminifera; these divisions can be recognized throughout the Middle East to the Far East, where the 'letter-stages' proposed by van der Vlerk for the Tertiary of Indonesia can be readily correlated with the European standard, and both may be correlated with the series of planktonic-foraminiferal zones erected by Bolli and others in the Caribbean. It is an inescapable fact that if the popular age-determinations of Central American middle Tertiary marine sediments are accepted, then that area is palæontologically out of step with the rest of the world. If sedimentation in Trinidad, for example, were really continuous from the Eocene to the Miocene (and the lower Cipero formation be regarded as Oligocene), then one can only conclude that the larger foraminifera (for example, *Miogypsina* s.s.), the planktonic foraminifera (for example, all species of the Globigerinidae which are stratigraphically relevant) and Mollusca (for example, by regional correlation, *Anadara*, *Chione*, *Timoclea*) occur at stratigraphically older horizons in America than anywhere else in the world. As there is no satisfactory evidence to the contrary, we believe that the occurrences of these fossils were isochronous, and that there occurred a major hiatus in the Caribbean sequence, a hiatus including at least the equivalent of the *Nummulites fichteli* beds of Europe ('c' and 'd' stages of the Far East), which contain (in Africa) a rich and distinctive assemblage of planktonic foraminifera, unrepresented in America. We have been able to trace the evolutionary history of many lineages of Globigerinaceae from the Upper Eocene to the Aquitanian in richly fossiliferous and well-dated sediments in East Africa; we have found that the Oligocene stages of these lineages are present in sediments of areas as far removed as western European and Indonesia–Australasia, but that these stages are conspicuously absent in America, between the Jacksonian and the Vicksburgian.

It has been known for decades that the Vicksburg formation rests disconformably on the Jackson, and that it contains in its lower beds (for example, the Red Bluff Clay) abundant re-worked fossils of the Eocene. It has been common knowledge that the sediments of Trinidad, far from constituting a "lithologically uniform sequence" as stated by Dr. Stainforth, have been repeatedly reported to contain boulder beds (with some 'boulders' up to 3,500 cu. ft. in volume), rubble beds with *Pholas*-bored pebbles, and re-worked fossils of Upper Cretaceous, Palæocene, Lower, Middle and Upper Eocene ages immediately above the horizon where we, on quite other (purely palæontological) grounds, would place the Miocene/Eocene unconformity. The San Fernando 'formation' we believe to be the basal bed of the Miocene transgression; far from being "firmly correlated with the Upper Eocene", as Dr. Stainforth suggests, our world-wide studies suggest that its fossil content is a mixed one, and that its youngest elements are characteristic of the Miocene. This does not conflict with the well-known fact that the lithology of the San Fernando 'formation', surrounding the re-worked boulders, is very close to that of the succeeding Cipero (into which it grades) but quite different from the underlying Navet; it is confirmed by our recognition of the lowest planktonic foraminiferal zones of the Cipero in acknowledged Aquitanian deposits elsewhere in the world.

It should be realized that many other widely held and long-established assumptions fundamental to mid-Tertiary dating in Central America (for example, the supposed Oligocene age of the Antigua Limestone coral fauna), when critically re-examined, prove to have little or no foundation in fact. The ages assigned to some species of several other groups of marine fossils (for example, Echinoidea, Bryozoa, Decapoda, etc.) from the Central American region will need revision in view of the evidence we shall present.

The known stratigraphical distribution of *Pliolepidina* depends on the interpretation of the morphology of that genus; we suspect that Dr. Stainforth has been led astray by W. Storrs Cole's misconceived treatment of *Lepidocyclina* and related genera. We redefine the relevant genera and restrict *Pliolepidina* to forms congeneric with *Multilepidina*, which is not known beneath the Miocene. It should be remembered in this context that no true *Nummulites* have ever been recorded above the Eocene in America, American post-Eocene *Nummulites*-like forms being referable to *Palaeonummulites* (which includes *Operculinella* and *Operculinoides*). With regard to the occurrences of *Echinolampas* and *Oligopygus*, *Echinolampas* ranges from Eocene to Recent, and *Oligopygus* occurs in the Eocene and also at levels at which Lower Miocene planktonic foraminifera occur, so that Dr. Stainforth's implication that they are Eocene indices does not seem wise. We should also like to place on record that the '*Rotalia*' *mexicana* group occurs as high stratigraphically as the Aquitanian in the Mediterranean region, and we believe it to range equally high in Central America. Also, it is mere hypothesis that this group (or even the genus *Neorotalia* to which it probably belongs) was ancestral to any of the Miogypsinidae, and even if this were found to be so, there would be no *a priori* reason to assume that the ancestral group would become extinct at the advent of its descendants.

The references for this study are so extensive, interrelated and mutually inconsistent (any brief selection would be misleading) that we can only refer the reader to the full discussion in our book, which contains a fully comprehensive bibliography, and which will soon be published.

Major Element Relationships in Tektites

The chemical composition of tektites is a major factor to be considered when investigating theories of tektite origin. Many investigators have remarked on the similarity of the composition of tektites to certain types of sedimentary rocks, and this fact has been held to be indicative of a terrestrial origin. Recent determinations[1] of the abundances of the alkali elements, lithium, sodium, potassium, rubidium and cæsium in australites showed that a close coherence existed between these five elements in different samples; in fact, the concentration of one alkali element was shown to be positively correlated with the concentration of any other to a high degree of significance.

Following on from this, it seemed worth while to investigate the possible correlations between the concentrations of other elements in tektites. This has been done, utilizing the published data for australites. A notable fact emerges, namely, that silica concentration is significantly negatively correlated with the concentrations of aluminium oxide, ferrous oxide, magnesium oxide, potassium monoxide and calcium oxide. By way of illustration we show the silica versus alumina graph (Fig. 1). The regression lines (silica on alumina and vice versa) have been drawn in, and it is interesting to note that both lines pass through 100 per cent silica to within 3 per cent. This fact, plus the presence of the well-known lechatelierite (fused silica) particles in tektites, suggested to us that tektite composition could perhaps be explained on the basis of a mixing process between

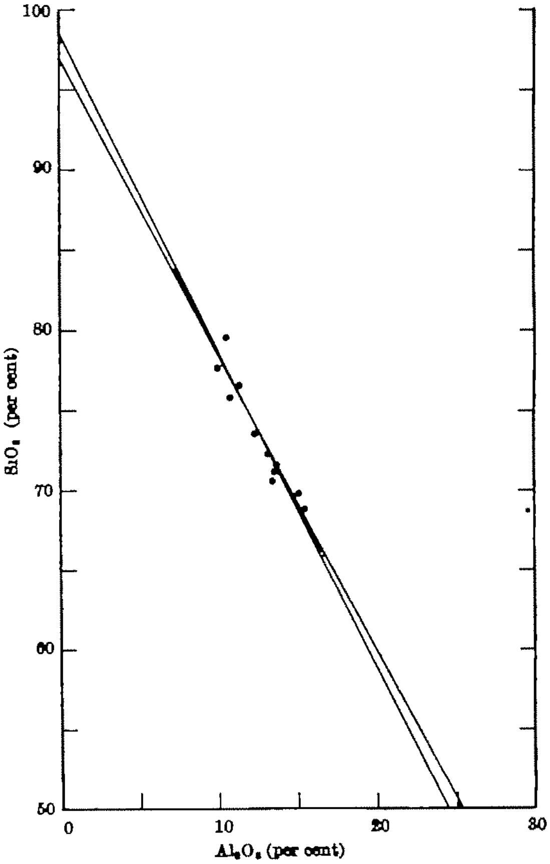

Fig. 1. Inverse relationship between silica (SiO_2) and alumina (Al_2O_3) for the australites. The regression lines are shown

silica and some other (unknown) material. A brief search suggested that the non-volatile (at 1,700° C.) constituents of ordinary shale would form a suitable 'unknown' material, and in Table 1 we give the chemical composition resulting from such a mixing process with a quartz : shale ratio of 1 : 3. Column 2 of the table must be compared with column 3, which gives the average tektite figures. The agreement is seen to be excellent, and it seems evident that a hypothesis that tektites are derived from a shale–quartz mix will explain the major element compositions of tektites. Shale and quartz are both extremely common terrestrial materials, and lack of availability will present no problem. The question of the mechanism of the mixing process remains. In this connexion we can present no evidence, though the Urey comet hypothesis[2] still seems to us to be a promising theory.

Table 1. COMPARISON OF COMPOSITION OF TEKTITES WITH THAT OF A MIXTURE OF SiO_2 WITH THE NON-VOLATILE (AT 1,700° C.) CONSTITUENTS OF SHALES

	1	2	3
SiO_2	64·32	73·24	73·73
TiO_2	0·72	0·54	0·86
Al_2O_3	17·05	12·79	12·47
FeO	6·72	5·04	4·92
MgO	2·70	2·03	2·12
CaO	3·44	2·58	2·50
Na_2O	1·44	1·08	1·32
K_2O	3·59	2·69	2·32
Total	99·98	99·99	100·24

Column 1. Composition of average shale from Pettijohn[3] (Table 61, p. 344) recalculated to 100 per cent following removal of water, carbon dioxide, SO_3 and organic matter.

Column 2. Composition of a mixture of three parts of column 1 with one part of silica.

Column 3. Average composition of 61 tektites from Barnes[4]. The analyses of Darwin glass and Libyan Desert glass quoted by Barnes[4] are excluded from this average.

The above results will be published in greater detail elsewhere, and discussed more fully.

PHYSICS

A Comparison of Atomic Beam Frequency Standards

STANDARD frequencies obtained from various cæsium atomic beam frequency standards have been compared in a number of instances[1–4]. The results of Holloway *et al.*[1] showed agreement to about 2×10^{-10} between the commercial beam standards developed and manufactured by the National Company and the atomic standard at the National Physical Laboratory, Teddington, England[4].

Two dissimilar beam standards at the National Bureau of Standards have been compared over the past several months. Their frequencies agree to within $\pm 1{\cdot}5 \times 10^{-11}$ (standard deviation of the mean for the comparisons and estimated uncertainty due to effects of pertinent parameters).

These machines employ Ramsey-type excitation, the separation of the oscillating fields being 55 cm. in one case and 164 cm. in the other. Beam dimensions are 0·003 in. × 0·100 in. and 0·015 in. × 0·187 in., respectively. The hot wire detectors (20 per cent iridium–platinum alloy) are used in conjunction with conventional electrometer circuits. Typical signal-to-noise ratios range between 100 and 400. The uniform magnetic *C* field in the transition region is produced by passing a d.c. current of about 1 amp. through a conducting section of a cylindrical brass tube contained within a magnetic shield. A double shield is used on the longer machine and a single shield on the shorter.

There are a number of uncertainties in absolute frequency measurements introduced by the measuring devices themselves. Those effects contributing most significantly to the overall uncertainty of the measurements are: (*a*) the magnitude and non-uniformity of the *C* field; (*b*) a phase difference between the two oscillating electromagnetic field regions; (*c*) a lack of purity of the electromagnetic field exciting the atomic transition.

The magnitude of the *C* field was determined in four different ways: by calculation from the known geometry of the conducting strip and the current used; by direct measurement using a rotating-coil fluxmeter sensitive to 0·002 oersted; by measurement of the low-frequency $\Delta F = 0$, $\Delta m_F = \pm 1$ transitions which are strongly dependent on the magnitude of the field; and by measurement of other microwave transitions, such as the $(F = 4, m_F = 1) \leftrightarrow (F = 3, m_F = 1)$ transition, which are more sensitive to the field than the standard frequency transition. The uniformity of the *C* field was determined by measuring the low-frequency transitions, utilizing small coils located at each end of the resonant cavity and at the centre of the transition region. These localized field measurements indicate that the maximum *C* field variation along its length is ± 0·002 oersted. This non-uniformity can introduce at most an uncertainty of 4×10^{-12} in the measured frequency. At the time of the initial comparisons of the two standards the values of the *C* field magnitude as measured by the different methods agreed to within the precision of the measurements (± 0·002 oersted) for both machines. Since that time, however, the shielding properties of the mumetal shields have deteriorated to some extent, accompanied in the case of the longer machine by a discrepancy among the various types of field measurements of about 0·004 oersted at a field of 0·080 oersted. In order to reduce the resulting uncertainty in the frequency measurements to below 1×10^{-11}, smaller *C* fields (about 0·020 oersted) have been used in the more recent comparisons. Possible frequency shifts arising from the nearness of other transitions at these low fields have been calculated and found to be well below 1×10^{-11} for the degree of symmetry of position and amplitude observed for the nearby transitions.

The oscillating fields exciting the $(F = 4, m_F = 0) \leftrightarrow (F = 3, m_F = 0)$ transition are produced at the two ends of a single resonant U-shaped rectangular cavity operating in the $TE_{0,1,66}$ mode for the shorter machine and in the $TE_{0,1,160}$ mode for the longer machine. The cavities were precisely electroformed for symmetry about the coupling hole to the microwave transmission line from the frequency multiplier chain. The atomic beam grazes the shorted end walls of the U-shaped cavity. Provision for tuning the cavities in the event of large room-temperature changes is provided by a tuning plunger opposite the coupling hole.

Frequency uncertainties introduced by a phase difference between the two ends of the cavity were investigated by rotating the cavity 180°, that is, by interchanging the two oscillating field regions. No frequency shift was measurable under this operation for either machine.

If the electromagnetic field exciting the transition is not pure, that is, if this signal is frequency modulated, rather large frequency uncertainties are possible in the measurements. The exciting radiation is ordinarily produced by frequency multiplication by a factor of 1836 from a stable quartz crystal oscillator. Side-bands in the power spectrum introduced in the oscillator or first stages of the frequency multiplier chain are enhanced significantly by the multiplication process. What is worse, side-bands resulting from frequency modulation are not, in general, symmetrically placed about the 'primary' signal. The power spectrum of the exciting radiation for the Bureau standards was examined using an ammonia maser stabilized frequency multiplier chain as a spectrum analyser[5]. The signal was found to have a bandwidth of about 6 c./s. at 9,000 Mc./s., was symmetrical and contained no observable side-bands. Any shift introduced from this source would be much less than the precision of measurement. In general, however, side-bands will be present to some extent. In one experiment where side-bands were deliberately introduced, the measured frequency was shifted by 3×10^{-9}.

The effects discussed above are those that we consider to contribute most significantly to the uncertainty of absolute frequency measurements if adequate care is not taken in construction and testing. We have found it possible to reduce these uncertainties to a level below 1×10^{-11}.

Initial comparisons of the two standards were made during a ten-day period with each daily comparison consisting of an average of from 15 to 25 measurements with each standard. If $\Delta\nu_i$ denotes the zero-field frequency difference between the two machines for the ith day, then the measured average difference for the ten-day period was:

$$<\Delta\nu>_{av} = \frac{1}{n}\sum_{i=1}^{n} \Delta\nu_i = 0, \text{ where } n = 10$$

The standard deviation of the mean for this particular test was:

$$\sigma_M = \frac{1}{\nu}\left[\frac{\sum_{i=1}^{n} (\Delta\nu_i - <\Delta\nu>_{av})^2}{n(n-1)}\right]^{1/2} = \pm 1{\cdot}6 \times 10^{-11}$$

The estimated uncertainties introduced by the effects discussed above fall within this precision. During later tests on the standards a more complete set of comparisons was obtained consisting of 18 separate comparisons taken over a period of one month. The average zero-field frequency difference for this period was 9×10^{-12} with a standard deviation of the mean of 6×10^{-12}. To this standard deviation was added the maximum uncertainty in frequency contributed by the C field (9×10^{-12}), giving $\pm 1{\cdot}5 \times 10^{-11}$ as the limits quoted for the agreement of the two machines. The uncertainty introduced by the discrepancy in the C field measurements noted above was reduced to less than 1×10^{-11} by using low fields. Since this discrepancy seems to be associated with a noticeable deterioration of the C field shielding, it is likely that for most precise results the shields will have to be exchanged periodically for newly annealed ones.

One indication of the reproducibility of measurements made with the longer machine was obtained by comparing eight separate sets of measurements of 'Atomichron 106' during an 8-hr. period. Each set or sub-group consisted of 15 measurements taken in a period of about 15 min. The standard deviation of the mean for each sub-group was 1×10^{-11}, while the standard deviation of the mean for the average of all the results was 5×10^{-12}. A similar experiment was conducted in which an extremely low-drift crystal oscillator with its crystal immersed in liquid helium was measured instead of the 'Atomichron'. These measurements gave 7×10^{-12} as the standard deviation of the mean for each sub-group and 2×10^{-12} as the standard deviation of the mean for the average of all the results taken during the period of several hours. The various parameters affecting the frequency measurements, then, are sufficiently constant that measurements can be made to a precision of 2×10^{-12} in periods of several hours or longer; however, uncertainty in the exact values of some of the parameters limits the accuracy to about $1{\cdot}5 \times 10^{-11}$.

The longer of the two machines is the present United States Frequency Standard. The shorter machine is an alternate standard[3]. The frequency assumed for the $(F = 4, m_F = 0) \leftrightarrow (F = 3, m_F = 0)$ transition of cæsium in zero field is 9192631770·0 c.p.s. The best comparison between cæsium and Ephemeris Time at present is that given by Markowitz, Hall, Essen and Parry as 9192631770 ± 20 c.p.s.[6].

Corrections for the 60 kc./s. standard frequency broadcasts of Station *WWVB* (formerly *KK2XEI*), Boulder, Colorado, are made each week and are available upon request.

We believe that the experiments demonstrate that with adequate care in construction and testing, atomic beam standards can be expected to agree in frequency without special recipes in design, and indeed they behave precisely as one would predict from theory—one need only know the values of the pertinent parameters to sufficient accuracy. This information must be obtained from appropriate tests.

Isotopic Analysis of Silicon by Solid-Source Mass Spectrometry using Negative Ions

An A.E.I. mass spectrometer, type *M.S.2/S.*, fitted with an electron multiplier and having a triple tungsten filament as source for the thermal ionization of solids is being used for measurements of the abundance of silicon isotopes.

The instrument normally records the amplified current peaks of positive ions. In the case of silicon, it has not been possible so far to detect a positive ion from thermal ionization, but after reversing the polarity of the accelerating voltage and magnetic field of the instrument, negative ions have been measured corresponding to SiO_3^- at values of m/e of 76, 77 and 78.

The filament source is loaded with an alkali silicate, and the best results are obtained from cæsium silicate. This is in accordance with the ionization potential of cæsium, which is the lowest for the natural alkali element series; thus no ions are obtained from sodium silicate and only small peaks from potassium silicate.

High-Energy Oxygen Ions in Carbon Dioxide Mass Spectra

Mass spectra of carbon dioxide have been recorded using a low accelerating voltage and magnetic scanning. Under these conditions, a variant of those due to Mohler *et al.*[1], ions with more than thermal energies will appear as satellite peaks in the spectra. The energies of the ions can then be derived from the separation of the peaks by the use of the mass spectrometer focusing equation.

A high-energy state in oxygen ions has been observed as a satellite on the high-mass side of the main peak due to thermal energy oxygen ions. The energy of this state in oxygen ions was found to be $3 \cdot 5_1$ V. when the energy of the ionizing electrons was 70 V. The apparent appearance potential was 35 V. (the voltage scale being corrected by the known value for the thermal energy peak of the oxygen ion[2].

These values would suggest that the ions were due to the dissociation of doubly charged ions[1]; those possible are O_2^{2+}, CO^{2+} or CO_2^{2+}. It will be seen that the appearance potential is lower than those found for O_2^{2+} from oxygen (50 V.) and for CO^{2+} from carbon monoxide, namely, 42 V. (ref. 2). Ions of O_3^+ were not detected under the present conditions; and thus if the mechanism is $O_2^{2+} \rightarrow 2\,O^+$, a previous reaction similar to one suggested by Ogryzlo and Schiff[3], namely, $CO_2 + O \rightarrow CO + O_2$, seems preferable to a rearrangement reaction involving O or a secondary reaction induced by pressure. The CO_2^{2+} mechanism, namely, $CO_2^{2+} \rightarrow CO^+ + O^+$, is the most probable, as CO_2^{2+} ions exist in the mass spectrum and the appearance potential of the O^+ ion state is comparable to that of CO_2^{2+} ions, about 36 V. by comparison with the known value for A^{2+} ions[2]. This reaction was also postulated by Newton[4] to explain other phenomena in the mass spectra of carbon dioxide. However, if the reaction is indeed $CO_2^{2+} \rightarrow CO^+ + O^+$, a definite energy-state would be expected in the CO^+ ions.

Only the main ion peak, together with high-energy tailing, was apparent in the C^+, CO_2^{2+} and CO^+ ion peaks. The main excitation energy found for O^+ ions from carbon monoxide under these conditions (70 V. ionizing electrons, 230 V. accelerating voltage) was $2 \cdot 4_2$ V., compared with Hagstrum's value of 1·5 V. by the retarding potential method and Berry's value of 0·65–2·5 V. by the deflexion method[2]. When ionizing electrons of 70-V. energy were used, the O^+ ion peak from oxygen showed a high-energy tail but no evidence of a discrete high-energy state.

The ratio between the ions of high-energy state and the thermal energy ions was affected by variations in the ion repeller voltage, which altered the time of residence of the ions in the ion chamber. Low voltages, down to 0·5 V., favoured the high-energy state, presumably because the time available for dissociation was increased, whereas higher voltages, up to 8 V., resulted in the predominance of the thermal-energy ions.

The mass spectrometer is a 10-cm. radius 90° deflexion A.E.I. instrument with a source of Nier type.

METALLURGY

Formation of Fayalite in Roast Reduced Jaspilite

A magnetizing roasting treatment of a fine-grained hæmatite-quartzite known as jaspilite, occurring in South Australia, is at present being evaluated[1]. When heated in reducing gases at appropriate temperatures, 550–650° C., the hæmatite in jaspilite is converted to magnetite. Extensive microcracking also occurs in the quartz matrix (Fig. 1*A*). This cracking allows freer access of reducing gases to the hæmatite particles undergoing reduction and facilitates grinding prior to magnetic concentration[2].

In contrast to prior investigations[3], roast reduction treatments much above 650° C. have led to lower rates of reduction, lower recoveries of magnetite, and less apparent cracking.

One reason for this, other than the effect of increased temperature in reducing the tendency of quartz to crack and part from the hæmatite, has been found to be the formation of fayalite ($2FeO.SiO_2$), by a solid-state diffusion reaction at the operating temperature.

That fayalite will form when hæmatite is reduced in the presence of silica at higher temperatures, 800–1,000° C., has previously been reported[4,5]. Indeed,

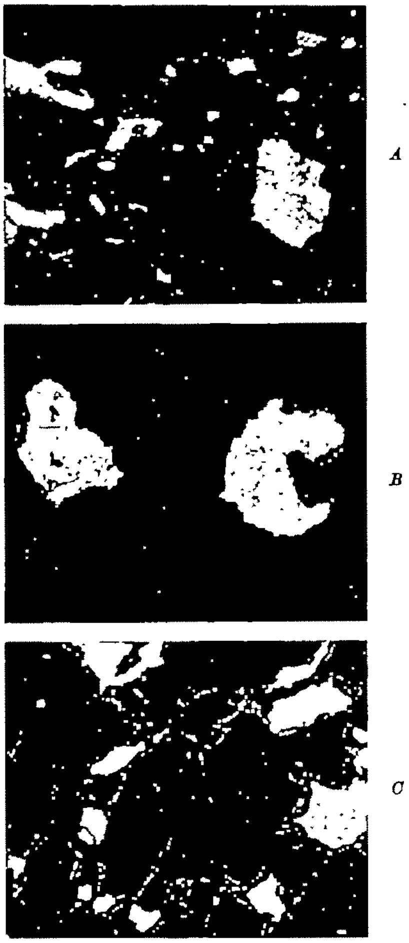

Fig. 1. Roast reduced jaspilite, vacuum mounted in epoxy resin, polished and examined, unetched, in reflected light : *A*, reduced in hydrogen at 550° C. for 10 min. Magnetite (grey) in a matrix of cracked quartz (dark grey) (× *c.* 330); *B*, reduced in 4 per cent carbon monoxide, 6 per cent carbon dioxide and 90 per cent nitrogen at 900° C. for 160 min. Fayalite forms at the magnetite-quartz, not at the hematite-quartz interfaces (× *c.* 660); *C*, reduced in hydrogen at 950° C. for 45 min. Over-reduction to wustite and fayalite. The fayalite fills cracks in the quartz. The resulting voids near the wustite have been filled with mounting resin (× *c.* 330)

Darken[6] has shown that, in the presence of an excess of silica, fayalite, not magnetite, becomes the stable phase under the reducing conditions normally employed.

This present work has shown that fayalite, formed at as low a temperature as 650° C., has the capacity to bond the magnetite and quartz, sealing the interface (Fig. 1*B*) and thus, by hindering access of reducing gases to the interior reduction zone, decreases the rate of reduction. Fayalite was identified by X-ray diffraction and by refractive index measurements.

The dihedral angle of fayalite in quartz has been found to be low, and at higher temperatures fayalite diffuses into, and fills, the microcracks (Fig. 1*C*). Non-magnetic fayalite adhering to silica and magnetite adds to the difficulties in effecting high recoveries of a high-grade concentrate in subsequent grinding and magnetic separation.

Further details of this work, including a discussion of the kinetics and mechanism of reduction cracking, will be published elsewhere.

Stabilization of Austenite by Hydrogen

Attempts to study the possible effects of hydrogen on the austentite–martensite transformation in steels have always to reckon with the difficulty of retaining adequate amounts of hydrogen in them, regardless of the amounts initially present. The austenitizing and heat treatment of steels are generally carried out at virtually atmospheric pressures or in vacuum. As the diffusion-rates of hydrogen at elevated temperatures are considerable, the amount of hydrogen retained in the austenite, prior to its being heat-treated, is generally small. It is also not so much in excess of the solubility limits as to render it likely that the hydrogen atoms play a part similar to that played by carbon atoms, which are generally retained in appreciable amounts and in a state of considerable supersaturation when the matrix changes to the body-centred structure. In the comparatively small amounts, therefore, in which hydrogen is retained in normally austenitized and heat-treated steels the likelihood of its affecting the stability of austenite may well be negligible (Ramachandran, E. G. and Dasarathy, C., unpublished work).

If, however, either a mode for austenitization and subsequent heat treatment of a steel with any specified, high amount of hydrogen can be devised, so as to retain adequate hydrogen in the austenite, or the hydrogen content of a normally heat-treated steel is increased when it is still austenitic and at a stage prior to its transformation to martensite, it may be possible to detect the effects of hydrogen on the austenite–martensite transformation. As austenitization in hydrogen at such high pressures as to ensure its adequate retention is, however, difficult to carry out (there is no guarantee even then, that hydrogen is not nearly completely lost by the austenite when it is cooled in salt, lead, oil or aqueous baths to transform to martensite) the first course does not appear to be feasible. The failure, therefore, by Ko and Edmondson[1] to detect any stabilization of austenite in a nickel steel, even when it was cathodically impregnated with hydrogen at room temperature but transformed after austenitization, 24 hr. after the impregnation, at 1,100° C. for 30 min. in vacuum, may well be understood.

The second alternative is quite feasible and allows the effect of hydrogen, when suitably introduced, on the stability of austenite to be studied, as may be seen from the following results, obtained on a 1·1 per cent carbon, 2·83 per cent chromium steel and a 18–8 low carbon (0·08 per cent) unstabilized stainless steel.

A. Chromium steel, austenitized in argon at 980° C. for 1½ hr. M_s temperature, 93° C. (approx.)

Heat treatment	Hardness (V.P.N., 30 kgm. load) (Mean of four impressions)
1. Quenched from 980° C. in boiling water at 98° C., held for 90 sec., and quenched in an aqueous solution of 10 per cent sulphuric acid, held at 18° C.	755
2. Quenched from 980° C. in an aqueous solution of 5 per cent sulphuric acid held at 98° C. for 15 sec., during which, using the bath as electrolyte, the specimen was cathodically impregnated, transferred to boiling water at 98° C. for 75 sec. and afterwards quenched in an aqueous solution of 10 per cent sulphuric acid, held at 18° C.	710
3. Quenched from 980° C. in an aqueous solution of 5 per cent sulphuric acid held at 98° C., subjected thrice to hydrogen impregnation and removal cycle as in 2 and finally quenched in an aqueous solution of 10 per cent sulphuric acid, held at 18° C.	710

B. Stainless steel, austenitized in argon at 1,050° C. for ½ hr. Approximate M_s temperature, −130° C.

Heat treatment	Hardness (V.P.N., 30 kgm. load) (Mean of four impressions)
1. Quenched from 1,050° C. in water at 18° C.	155
2. Quenched from 1,050° C. in water at 18° C., held at room temperature for 40 min., quenched in liquid air (−196° C.) and upquenched to water at 18° C.	169
3. Quenched from 1,050° C. in water at 18° C., transferred to an aqueous solution of 5 per cent sulphuric acid and cathodically impregnated for 40 min., quenched in liquid air and upquenched to water at 18° C.	164
3a. Above specimen aged at room temperature for 60 hr.	162
4. Quenched from 1,050° C. in water at 18° C., cathodically impregnated for 40 min., as in 3, transferred to boiling water at 98° C. for 75 sec., quenched in liquid air and upquenched to water at 18° C.	158

The above stabilization of austenite by hydrogen and the conditions under which it is detectable can be theoretically worked out from the concepts regarding austenite stabilization put forward originally by Cohen *et al.*[2], and amplified by us[3,4] and will be discussed in a subsequent communication.

We thank Dr. B. R. Nijhawan, director of the National Metallurgical Laboratory, Jamshedpur, for discussion and permission to publish this communication.

Retained Austenite and the Tempering of Martensite

THE decomposition of retained austenite as the second stage in the tempering of quenched steels is well recognized, and has been explored extensively. However, the role of retained austenite in the first stage tempering reaction has not been studied widely. That this may not be a passive role is suggested by the infrequent reports that a change in austenite chemistry by carbon enrichment accompanies this stage of tempering[1-3].

The first-stage tempering reaction takes place within the martensite platelets and occurs quite rapidly without the need for an induction period[4,5]. This process appears to occur discontinuously by the precipitation of ϵ carbide and the creation of a low-carbon martensite containing approximately 0·25 per cent carbon[3-5]. That is, the original supersaturation of the martensite is not relieved completely during the first-stage reaction. Normally, it is not until the third stage of tempering that the supersaturation of this low-carbon martensite is reduced further by the precipitation of the more stable carbide—cementite.

The reason for a matrix carbon content in the 0·2–0·3 per cent carbon range has received two divergent interpretations based on metastable equilibrium concepts. One view[4,5,7] ignores any interaction between martensite and retained austenite and assumes that the matrix carbon content is dictated by a metastable equilibrium between ϵ carbide and the low-carbon martensite. Alternatively[6], the matrix carbon content may be determined by a metastable equilibrium between ferrite (low-carbon martensite) and supercooled (retained) austenite. The latter concept is based on extrapolation of the ferrite (*GP*) and austenite (*GS*) solubility curves on the Fe—C equilibrium diagram. In effect, these two interpretations represent alternate means whereby the supersaturation of martensite may be lowered. In this sense, they compete with the more stable equilibrium involving cementite, and kinetic factors will determine the relative importance of each of the three reactions in the overall decomposition sequence. The part played by the ϵ carbide and cementite reactions is recognized clearly as the first and third stages of the tempering process; however, interaction with the retained austenite requires further clarification.

One of the critical points in deciding between these two interpretations of the matrix carbon content centres around the extrapolation of the ferrite and austenite solubility lines. It seems likely that these curves will exhibit retrograde behaviour[6] so that the solubility of carbon in ferrite (in metastable equilibrium with austenite) should be much less than 0·25 per cent carbon. Under this condition, it must be presumed that the 0·25 per cent carbon-level is controlled by metastable equilibrium with ϵ carbide. Nevertheless, when a martensite plate is surrounded by austenite, this low-carbon martensite should transfer much of its excess carbon to the austenite in an effort to achieve the lower carbon content demanded by the ferrite–austenite equilibrium. Thus, it should be possible to distinguish between these two interpretations of the matrix carbon content by studying the influence of retained austenite on the first stage tempering reaction.

According to this concept, martensite plates surrounded by austenite should lower their carbon content (below 0·25 per cent carbon) much more rapidly than those surrounded by other martensite plates. To check this possibility, two samples of a 9395 steel (composition: 0·95 per cent carbon, 0·22 per cent silicon, 0·60 per cent manganese, 3·07 per cent nickel, 1·23 per cent chromium, 0·13 per cent molybdenum) were prepared with different austenite–martensite ratios. Both samples were quenched in water after 24 hr. at 2,400° F. This produced 40–50 per cent martensite. One of these

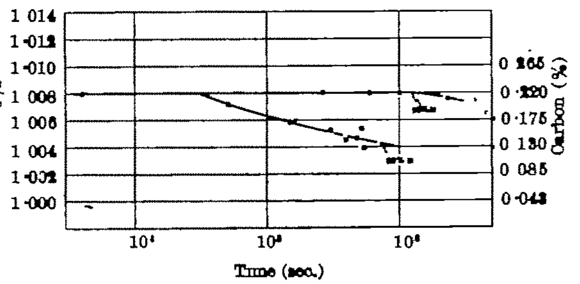

Fig. 1. Percentage of carbon in martensite as a function of holding time at 270° F.

samples was cooled immediately in liquid nitrogen which increased the amount of martensite to 90 per cent. The oscillating crystal technique of Kurdyumov and Lysak[5] was employed to determine the carbon content of the martensitic matrix after appropriate tempering treatments at 270° F. Fig. 1 illustrates the influence of retained austenite on the carbon content of the matrix of tempered martensite.

In this steel, the first stage tempering reaction initially yields a matrix composition of 0·22 per cent carbon regardless of the amount of retained austenite. However, the matrix carbon content of crystals containing 50 per cent martensite was lowered below this level much more rapidly than that of crystals containing 90 per cent martensite. X-ray diffraction studies demonstrated that virtually no additional transformation of austenite accompanied these tempering treatments and that the retained austenite was enriched significantly in carbon. Thus, it is apparent that austenite does act as an effective sink to drain the excess carbon from the martensitic matrix.

The partition of carbon from martensite to austenite indicates that the composition of the low-carbon martensite must be attributed to the metastable equilibrium involving ε carbide rather than the one involving retained austenite. In fact, it seems likely that re-solution of ε carbide helps to maintain the carbon-levels at the values reported in Fig. 1. Furthermore, this interpretation is consistent with the observation[10] that steels containing less than 0·2 per cent carbon do not undergo the normal first stage tempering reaction involving the precipitation of ε carbide.

The partition of carbon from martensite to austenite may contribute significantly to property changes associated with tempering. Generally, this has not been recognized in the analysis of reaction curves obtained by measuring property changes such as electrical resistivity, change in length, evolution of heat, etc. It is apparent that tempering is more complicated than the current theoretical treatments predict, so that a re-examination of tempering kinetics in the light of this and other phenomena may provide a deeper and more satisfying understanding of the theory of tempering processes.

These results also have an important bearing on the bainitic mode of austenite decomposition. The presence of ε carbide in low-temperature bainite[6] suggests that this transformation product passed through a decomposition sequence closely related to that in the formation and tempering of martensite. However, the demonstration that the matrix of low-temperature bainite contains approximately 0·1 per cent carbon rather than 0·25 per cent carbon appears to deny this relationship and suggests that bainite may bypass the tetragonal state characteristic of martensite[7].

This apparent anomaly is removed by the results presented in Fig. 1. Since bainite plates grow slowly[8], partition of carbon from bainite to austenite can accompany the growth process. In this light, it is suggested that low-temperature bainite forms initially (at the advancing tip of the plate) as a supersaturated ferrite with a carbon content which may not differ greatly from that of the parent austenite. Much of this supersaturation is lost rapidly by the precipitation of ε carbide which locally could result in a matrix carbon content in the 0·2–0·3 per cent carbon range. However, as growth of the plate continues, the excess carbon can escape to the surrounding austenite in much the same way as that demonstrated for the tempering of martensite in the presence of large amounts of retained austenite.

Thus, the low carbon content of the matrix of bainite is quite consistent with a supersaturated ferrite mechanism for the mode of formation of bainite.

We wish to express our appreciation to the Office of Naval Research, U.S. Navy, for support of this work.

CHEMISTRY

Recombination of Oxygen Atoms in the Gas Phase

THE rate of gas phase recombination of oxygen atoms at 10° C. in a flow system has been measured. The experimental method was essentially that described by Schiff[1]. Oxygen atoms were produced from electrolytic gas containing a small percentage of water vapour by passage through a microwave discharge. The decay of oxygen atom concentration along the axis of a cylindrical 'Pyrex' tube, 4 cm. in diameter and 100 cm. long, was followed by a movable isothermal probe similar to that used by Schiff[1]. Linear flow-rates in the range 60–250 cm./sec. and total pressure of 0·3–2 mm. mercury were employed. The initial atom concentration, estimated from the power input to the probe, was of the order 5–10 per cent.

The decay process was found to be first-order in oxygen atoms, but second-order in oxygen molecules.

This conclusion is in agreement with that of Schiff and supports his proposed mechanism :

$$\begin{array}{lr} O + O_2 + O_2 \rightarrow O_3 + O_2 & k_1 \\ O + O_3 \rightarrow 2O_2 & k_2 \\ O \rightarrow \tfrac{1}{2}O_2 \text{ wall} & k_3 \end{array}$$

If a stationary state is assumed for $[O_3]$, then :

$$\frac{-\,d[O]}{dt} = [O]\left\{2k_1[O_2]^2 + k_3\right\}$$

The theoretical model employed by us in evaluating k_1 and k_3 assumes one-dimensional flow and includes axial diffusion but neglects radial diffusion (on the grounds that the radial concentration gradient is probably very small[3]).

For a first-order reaction, the equation of continuity for the reacting species for a steady state is :

$$-D\frac{d^2n}{dx^2} + V_0\frac{dn}{dx} + k_e n = 0 \qquad (1)$$

where D is the binary diffusion coefficient, V_0 is the linear flow speed, n is the concentration of the reactive species and k_e is the rate constant for the reaction. This equation neglects the small change in V_0 over the reaction zone. The solution of (1) subject to the boundary conditions :

$$n = 0 \text{ at } x = \infty,\ n = n_0 \text{ at } x = 0$$

is

$$n = n_0\, e\, \frac{-kx}{V_0}$$

where

$$k_e = k\left(1 + \frac{kD}{V_0^2}\right) \qquad (2)$$

k/V_0 is thus the slope of the conventional log n versus distance plot shown in Fig. 1. For the proposed mechanism $k_e = (2k_1[O_2]^2 + k_3)$. When $\frac{kD}{V_0^2} \ll 1$, $k \simeq k_e$. Plots of $kv[O_2]^2$ and $k_e v[O_2]^2$ are shown in Figs. 2 and 3. Fig. 2 shows a distinct deviation from linearity, which is largely eliminated in Fig. 3, in which a value of $D = 2 \cdot 69 \times 10^2/p$ (p = pressure in mm. of mercury) has been used. This value of D has been estimated by Andrussov[3] on a theoretical basis.

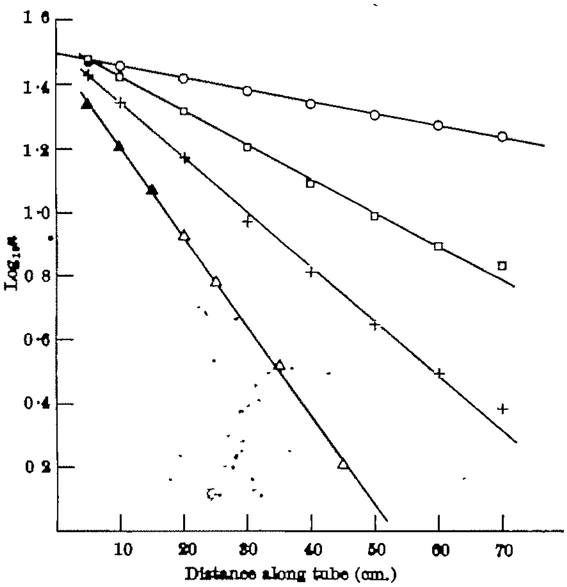

Fig. 1. Plot of log n versus distance for different total pressures. ○, p = 0·335 ; ■, p = 0·625 ; +, p = 0·797 ; △, p = 1·015 mm. mercury

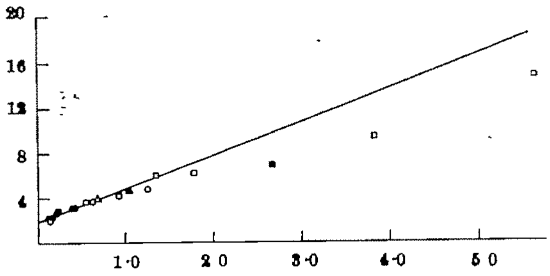

Fig. 2. Plot of k versus Po_2^2 (no diffusion correction), where the mass flow-rates of oxygen are as follows. △, 3 19 × 10^{19} molecules/sec. ; ○, 3·82 × 10^{19} molecules/sec. ; ■, 4 87 × 10^{19} molecules/sec.

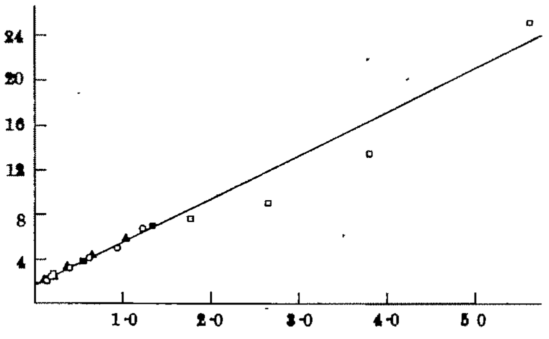

Fig. 3. Plot of k_e versus Po_2^2 (diffusion correction made). The oxygen flow-rates are as for Fig. 2

The values of k_1 and k_3 obtained from the data incorporated in Fig. 3 using equation (2) were :

$$k_1 = 6 \cdot 0 \times 10^{14} \text{ c.c.}^2 \text{ mole}^{-2} \text{ sec.}^{-1}$$
$$k_3 = 1 \cdot 7 \text{ sec.}^{-1}$$

The value of k_3 can be readily converted into a dimensionless recombination coefficient $\gamma = 2k_3R/\bar{c}$ (where R is the radius of the tube and $\bar{c}$ is the mean speed of the atoms), whence $\gamma = 1 \cdot 1 \times 10^{-4}$.

If no correction for diffusion were made and k_e were put equal to k (as was done by Schiff), then the corresponding approximate values from the data in Fig. 2 would be :

$$k_1 = 4 \cdot 6 \times 10^{14} \text{ c.c.}^2 \text{ mole}^{-2} \text{ sec.}^{-1}$$

$$k_3 = 1 \cdot 9 \text{ sec.}^{-1}\ (\gamma = 1 \cdot 2 \times 10^{-4})$$

Schiff found $k_1 = 1 \cdot 0 \times 10^{14}$ c.c.^{2} mole^{-2} sec.$^{-1}$ and $\gamma = 0 \cdot 77 \times 10^{-4}$.

A recent investigation of the kinetics of this reaction followed by paramagnetic resonance has been made by Strandberg *et al.*[4]. If their data are analysed on the basis of the theoretical model used here, the reaction appears to be roughly first-order with k in the range 22·0–38·0 sec.$^{-1}$, the total oxygen pressure being 5 mm. mercury. Correcting for diffusion according to equation (2), k_e is found to be in the range 27–42 sec.$^{-1}$. Using Strandberg's quoted values of $\gamma = 3 \cdot 2 \times 10^{-4}$, $R = 0 \cdot 5$ cm., k_1 is evaluated by us as 0·6–1·8 × 10^{14} c.c.^{2} mole^{-2} sec.$^{-1}$.

Other recent values of k_1 reported in the literature are : 2 × 10^{14} (Kaufmann[5]) ; 0·79 × 10^{14} (Benson and Axworthy[6]) ; ∼ 10 × 10^{14} (Steinberg *et al.*[7]).

A comprehensive theoretical treatment of the appropriate flow problem, including the effects of viscosity, pressure gradients, axial and radial diffusion and chemical reaction, is extremely difficult to handle, but the simplified model presented here appears to describe the experimental situation fairly adequately in this case. It appears important to us that some correction for axial diffusion along these lines should be made when the quantity $\frac{kD}{V_s^2} > 0{\cdot}1$.

Use of Reflectance Measurements in assessing the Colour Changes of Ageing Bloodstains

IT is well known that the colour of bloodstains changes from red to brown with increasing age; but the rate at which these changes occur and the factors which influence this rate are not so well established[1–3]. This is probably in part due to the use of subjective visual assessment of the changes. Extraction of the bloodstains and subjecting the extracts to spectrophotometric analysis suffers from the defect of being destructive of the stain and is sometimes complicated by simultaneous extraction of dye and dirt from the stained object. There is also evidence that the extraction methods may accelerate the colour changes (Kind, S. S., unpublished results).

The value of being able to assess the age of bloodstains, even within wide limits, can on occasion be useful. For example, a person accused of assault may allege that bloodstains present on his clothing are his own, of long standing, and resulted from a cut while shaving. Age assessment may help here if grouping tests prove of no assistance.

The development of photo-electric colorimeters of high sensitivity and precision, the readings of which can be readily converted to the C.I.E. system of colour specification[4], offers a method of non-destructive testing, based on the surface colour of the stain, and free from any subjective judgment.

To test this view, stains were prepared as follows. Sufficient fresh venous blood was collected from six male individuals (age-range 17–45 years) to cover an area rather greater than 4 cm. × 2·5 cm. in the middle of a Whatman No. 1 filter paper circle. When dry the circle was then cut exactly to 4 cm. × 2·5 cm. to eliminate differential shrinkage of the paper which otherwise made it difficult to press the stained area flat without any wrinkling. The samples were then fixed with small pieces of adhesive tape to the back of a black metal mask with an aperture 3·0 cm. × 2·0 cm. cut in it. Marked into the metal of the mask was a rectangle of exactly the same size as the stained paper so that the samples could be placed in exactly the same position on the 'Colormaster' differential colorimeter on each occasion that their colour was measured. Over the back of the samples and the mask a piece of black velvet fixed to black 'Perspex' was placed. This served to exclude light reflected from the back of the samples and to keep them flat.

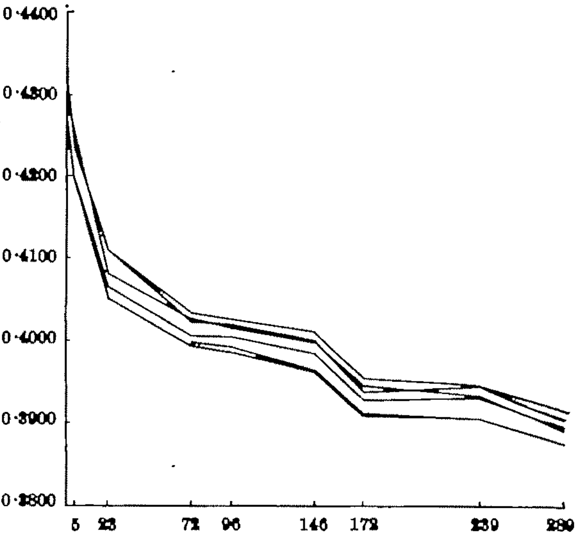

Fig. 1. The ordinate refers to the x co-ordinate on the C.I.E. system. The abscissa refers to the duration of the experiment in hours

The C.I.E. chromaticity co-ordinate x obtained for the six stains is presented in graphical form (Fig. 1). The chromaticity co-ordinate y showed little change over the period of the experiment apart from a slight but steady increase (mean 0·3280 increasing to 0·3330) and the luminance factor after an initial small drop in the first 24 hr. remained constant. The precision of a single reading was estimated by taking 12 successive sets of readings of the red, green and blue reflectance values on one bloodstain, the sample being removed and replaced on the mask between each set. The means and standard deviations obtained are shown in Table 1.

Table 1

	Mean reflectance (per cent)	Standard deviation
Green	13·046	0·013
Red	17·752	0·018
Blue	8·832	0·011

This shows very high precision quite adequate for the purpose in hand.

From Fig. 1 it can be seen that the changes in colour can best be followed from the x chromaticity co-ordinate and that the greater part of the change takes place in the first three days. Afterwards the rate of change is small, and is such that the daily change would only be detectable by a trained observer who had both the changed and unchanged colour before him at one time. It therefore seems unlikely that it is possible to tell the age of bloodstains by visual means alone with any certainty.

The conditions of temperature, humidity and lighting under which the stains are kept doubtless have an effect on the rate of colour change. In these experiments the stains were kept in the dark at room temperature (about 18° C.) between measurements. The use of high-precision colorimetry would seem to offer a basis for preparing master curves of colour changes against time for different environmental conditions and thus by measuring the rate of change of the colour of an unknown sample to estimate its age by extrapolation. Not enough results are, however, available from the present investigation to enable this to be done.

I wish to thank Mr. S. S. Kind, of the Home Office Forensic Science Laboratory, Harrogate, for helpful discussions.

Determination of Fatty Acids of Lower Molecular Weight by Gas Chromatography

ANALYTICAL methods for the qualitative and quantitative analysis of fatty acids have been concerned primarily with the fatty acids of higher molecular weight because of their importance in health and nutrition. Small quantities of fatty acids as the methyl esters can be separated by the gas-liquid partition chromatography of James and Martin[1,2]. The fractionation is based on the length of the carbon chain with the more recent development, including fractionation on the basis of unsaturation[3-5]. These methods, however, do not provide for the convenient analysis of the acids of lower molecular weight in a mixture of fatty acids. By modification of the method of Craig and Murty[5] it is possible to separate and identify the fatty acids of lower molecular weight with the same column as that used for the separation of the acids of higher molecular weight.

An 'Aerograph' gas chromatographic instrument, model A-100, was employed for the fractionation of the methyl esters of the fatty acids. The stainless steel column, ¼ in. outer diameter and 10 ft. long, was packed with 'Chromasorb', 60–80 mesh (Johns-Manville, Celite Division, New York), impregnated with polyester butanediol succinate[5]. 5 gm. of the polyester dissolved in 200 ml. of acetone were added to 25 gm. of 'Chromasorb'. The acetone was removed by heating on a steam-bath, after which the mixture was dried in an oven at 110° C. for 6 hr. A filament current of 210 m.amp. was maintained on the standard 'Aerograph' four-filament detector. A 'Varian' 10 mV. recorder was modified with a range selector switch to give a 1 mV. full-scale sensitivity.

The original procedure was modified for the separation of the lower molecular weight esters. A known mixture of fatty acids, consisting of acetic, propionic, *iso*butyric, butyric, 2-methyl butyric, *iso*valeric, valeric, *iso*caproic, caproic, œnanthic, and caprylic acids, were converted to the corresponding methyl esters by reaction with diazomethane, using the microtechnique of Roper and Ma[6]. Since these esters would be characterized by lower boiling points, the column was maintained at a temperature of 92° C. with helium used as the carrier gas at a flow-rate of 40 ml. per min.

A chromatogram showing the separation of these lower molecular weight fatty acid esters is shown in Fig. 1. Using this technique, it is possible to separate the lower molecular weight fatty acids in approximately 28 min.

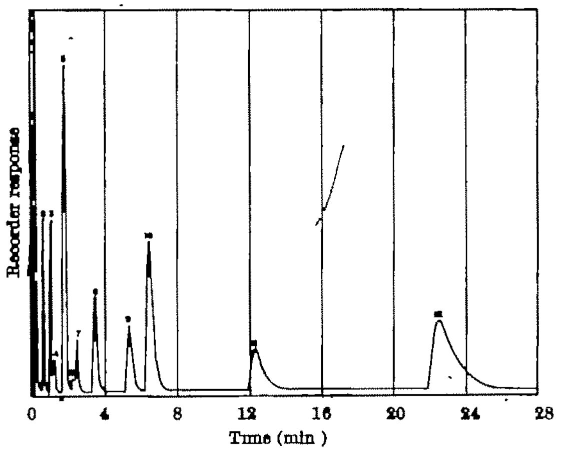

Fig. 1. Separation of lower molecular weight fatty acid esters. 1, Solvent (diethyl ether); 2, methyl acetate; 3, methyl propionate; 4, methyl *iso*butyrate; 5, methyl butyrate; 6, methyl-2-methylbutyrate; 7, methyl *iso*valerate; 8, methyl valerate; 9, methyl *iso*caproate; 10, methyl caproate; 11, methyl enanthate; 12, methyl caprylate. Efficiency: 3,320 theoretical plates (methyl caprylate)

The separation of the higher molecular weight fatty acids can be accomplished by raising the temperature to 216° C. and increasing the flow-rate to 60 ml. per min. The column is brought to equilibrium and another sample injected into the column.

By comparing the peak area of an ester such as methyl caprylate which appears on both chromatograms it is possible to establish a quantitative relationship between the lower and higher molecular weight fatty acids. If no peak overlaps, the addition of a known amount of methyl caprylate will establish a reference point.

BIOCHEMISTRY

Microbiological Transformation of Terpenes: Hydroxylation of α-Pinene

THE microbiological transformations of steroids and alkaloids have opened up a new line of approach towards the synthesis of many biologically active compounds. Relatively little is known, however, about the capability of micro-organisms to transform the simple terpenoid compounds. Recently, Bradshaw *et al.*[1,2] have studied the microbiological transformation of camphor.

The yields of essential oils from some oil-bearing plants are known to be considerably enhanced if the plants are infected by micro-organisms[3]. The present communication deals with the microbiological transformations of α-pinene by moulds.

A preliminary screening of fungi on Czapek–Dox medium enriched with yeast-extract, corn-steep liquor and 0·5 per cent α-pinene (I) resulted in the selection of a strain of *Aspergillus niger* for further studies. A 24-hr. shake culture of this strain metabolized 0·5 per cent pinene in 4–8 hr.

In a typical fermentation the mould was grown in shake cultures for 24 hr. *d*-α-Pinene (I) was added to the culture (0·5 ml. per 100 ml. of the medium) and the fermentation was continued for 4 hr. (The purified sample of α-pinene employed in these experiments had a rotation of $[\alpha]_D^{25}$ + 24·5°. This rotation would correspond to a mixture of 70 per cent *d*- and 30 per cent *l*-α-pinene.) After this period a second lot of pinene (0·5 per cent) was added and the fermentation was allowed to proceed for another 4-hr. period. The culture was filtered. The mycelial pellets were extracted with a little acetone and the acetone extract was added to the culture filtrate, which was then extracted first with ether (extract *A*) and then with butanol (extract *B*). Extract *A* was washed free from acids by aqueous sodium carbonate and evaporated to yield a pale yellow oil. Unreacted pinene was removed from this oil by a countercurrent distribution between hexane and 90 per cent aqueous ethanol. The ethanolic layers containing the oxygenated conversion products of pinene were carefully evaporated. The oily residue yielded on distillation, under reduced pressure, a clear, colourless oil and a semi-crystalline residual mass.

The distillate was further fractionated into an alcohol (II) and a ketone (III) by bisulphite treatment. The residue in the distillation flask, as well as the butanol extract (extract *B*), yielded a crystalline diol (IV) on chromatography over alumina.

Alcohol II: b.p. 140° (bath temp.)/16 mm. $[\alpha]_D^{25}$ + 64° (alcohol); molecular formula $C_{10}H_{16}O$ (found, C, 78·62, H, 10·6); infra-red absorption 3,420 cm.$^{-1}$ (OH). It gave a crystalline *p*-nitrobenzoate, m.p. 90° $[\alpha]_D^{25}$ + 14° (alcohol).

On mild chromic acid oxidation in pyridine or by oxidation with solid manganese dioxide in chloroform the alcohol (II) yielded the ketone (III) in nearly quantitative yields.

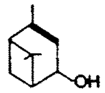
Ketone (III): b.p. 130° (bath temp.)/14 mm. $[\alpha]_D^{25}$ + 223° (ethanol); molecular formula $C_{10}H_{14}O$ (found, C, 79·82, H, 9·51); ultra-violet absorption $\lambda_{max.}$ 253 mμ ($\epsilon_{max.}$ 6,480); infra-red absorption 1,665 cm.$^{-1}$ (conjugated C═O) and 1,615 cm.$^{-1}$ (double bond). It formed a semicarbazone m.p. 203–205°.

From these properties the ketone (III) was identified as *d*-verbenone. For comparison *d*-verbenone was synthesized according to the method of Badoche[4]. A comparison of the physical properties, ultra-violet and infra-red spectra of verbenone and its semicarbazone with those of the ketone (III) and its corresponding derivative conclusively established the identity of compound III. There was no depression in the mixed melting point of the semicarbazones. The alcohol (II) could, therefore, be characterized as *cis d*-verbenol on the basis of its optical rotation and the melting point and the optical rotation of its *p*-nitrobenzoate[5].

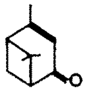
Diol (IV): m.p. 144–145° $[\alpha]_D^{25}$ + 152° (ethanol); molecular formula $C_{10}H_{18}O_2$ (found, C, 70·66; H, 10·7); strong infra-red absorption at 3,260 cm.$^{-1}$ (OH). It was identified as *d*(+)-*trans*-sobrerol on the basis of the following properties:

It showed no depression in the mixed melting point with synthetic *trans* sobrerol prepared by acid-catalysed rearrangement of α-pinene epoxide[6]. The physical properties and the infra-red spectra of (IV) were identical with those of the synthetic product. Both were converted to the identical ketone, hydroxycarvotonacetone (V) ($\lambda_{max.}$ 232 mμ, $\epsilon_{max.}$ 9,200), on oxidation with manganese dioxide.

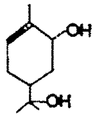
I
α-Pinene



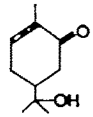
II
cis-Verbenol



III
Verbenone



IV
trans-Sobrerol



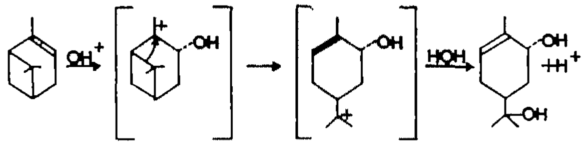
V
Hydroxycarvotonacetone

Under optimum conditions the yields of these products on the basis of the pinene utilized were 20–25 per cent verbenol, 2–3 per cent verbenone and 2–3 per cent sobrerol. The major fraction of the pinene metabolized appears to have been broken down to smaller fragments and probably oxidized to carbon dioxide and water.

Verbenone, verbenol and sobrerol have been identified among the auto-oxidation products of α-pinene. The major product of auto-oxidation is, however, verbenone with only small amounts of the alcohol, whereas verbenol is the major metabolite obtained by microbiological oxidation. Moreover, in the biological process these products were obtained in optically pure form, presumably from *d*-α-pinene.

The formation of *cis*-verbenol may be accounted for either by a free-radical attack at the allylic position, or by removal of a hydride ion from the same position through the mediation of an electrophilic species, such as an incipient OH⁺.

d-*trans*-Sobrerol may be presumed to be derived from *d*-α-pinene by a postulated attack on the 1,2 double bond by an electron deficient oxygen (OH⁺, etc.) in the following manner:



A detailed report on these investigations will be published elsewhere.

We wish to express our thanks to Drs. S. C. Bhattacharyya and V. Jagannathan for their interest in this work and helpful suggestions.

Excretion of Catechol after Ingestion of Quinic and Shikimic Acids

THE detection of catechol in acid-hydrolysed normal human urine and cow's urine was reported recently by von Euler and Lishajko[1]. The origin of the catechol was not known. The excretion of hippuric acid in the urine of man after oral ingestion of calcium quinate was reported by Lautemann in 1863[2]. It occurred to us that if an aromatic ring can be formed in the animal body from quinic acid (1 : 3 : 4 : 5-tetrahydroxy*cyclo*hexane carboxylic acid), then urinary catechol might have a similar origin. Further, an exogenous (dietary) precursor is implicated since we are unable to detect catechol in the urine of rats fed a highly purified diet. Quinic and shikimic acids are known to be present in edible plants.

Adult albino rats were fed a purified diet (sucrose, casein, salts, oil, vitamins) and given quinic acid by stomach tube (100 mgm./rat). A 48-hr. urine sample was collected and subjected to two-dimensional paper chromatographic analysis. The lower phase of a chloroform/acetic acid/water (2 : 1 : 1) mixture was used in the first direction followed by 20 per cent potassium chloride in the second direction. Each developed chromatogram was air-dried and carefully examined under short-wave ultra-violet light and then sprayed with diazotized sulphanilic acid followed by 20 per cent sodium carbonate. Thus the positive identification of a urinary metabolite was based on its R_F values in two dimensions, its behaviour under ultra-violet light and its colour with diazotized sulphanilic acid–sodium carbonate.

In our chromatographic system[3] hippuric acid is located at R_F 0·60 × 0·87, gives no colour with the diazotized sulphanilic acid reagent and absorbs ultra-violet light. The only notable deviation from normal in the case of the ether extract of the acidified urine of rats given quinic acid by stomach tube was a marked increase in the size of the area corresponding to hippuric acid. Catechol was not detected. Similarly, catechol was not detected after acid hydrolysis (2 *N* hydrochloric acid reflux, 30 min.) of the ether extract, suggesting that this fraction does not contain an ether-soluble conjugate of catechol. Finally, the ether-extracted urine was acid-hydrolysed and re-extracted with ether. When this ether extract was examined chromatographically, catechol was readily detected at R_F 0·50 × 0·74. Catechol absorbs ultra-violet light and when sprayed with the diazotized sulphanilic acid reagent undergoes a very characteristic colour change from red to green to blue-black. Another characteristic of catechol is its tendency to darken on an unsprayed chromatogram, presumably due to spontaneous oxidation.

When shikimic acid was administered to rats by stomach tube (100 mgm./rat) the same results were obtained as described above for quinic acid. Thus catechol was clearly present on the chromatogram of the acid-hydrolysed ether-extracted urine. In addition, an unidentified metabolite of both quinic and shikimic acids having the same chromatographic characteristics as vanillic acid was detected in the urine after hydrolysis.

Rats were also fed quinic acid mixed in the purified diet at a level of 3 per cent. Catechol was readily detected free (unconjugated) as well as conjugated in the urine. According to Garton and Williams[4], catechol is formed and excreted principally as a monoglucuronide or monosulphate derivative in the urine of rabbits receiving benzene by stomach tube.

It is difficult to estimate the amount of catechol excreted in urine, due to its instability, especially when subjected to acid hydrolysis. A minimal amount of 2 mgm. of catechol was excreted during a period of two days by two rats ingesting a total of 1·5 gm. of quinic acid in the diet.

Whether aromatization of quinic and shikimic acids to form catechol is dependent on intestinal micro-organisms is not known. Ayengar *et al.*[5] reported that "extracts of rabbit-liver acetone powder catalysed the formation of catechol from 3,5-*cyclo*hexadiene-1,2-diol", but not from D-quinic acid. Mitoma *et al.* isolated an enzyme system from guinea pig liver which was able to aromatize *cyclo*hexanecarboxylic acid[6].

From these results it is tempting to conclude that the catechol in human and cow urine may be formed from quinic acid and related substances in the diet.

Staining for Iodine in Chromatograms of Human Plasma : an Artefact due to Thiourea or Thiouracils

UNTIL the report by Werner and Block[1], it was generally thought that at most only very small quantities of iodinated tyrosines are present in normal human serum. This conclusion was based on ^{131}I-chromatographic studies using plasma extracts from subjects given radioiodine. Werner and Block report, however, that when the iodine distribution in normal human serum is analysed chemically by the ceric–arsenite reaction[2], approximately half the circulating iodine is present in the form of mono-iodotyrosine or di-iodotyrosine, although the radioactivity in the same chromatogram is distributed according to the results of other workers. Hitherto these results have been very difficult to understand, and they are inconsistent with the rapid deiodination seen when iodotyrosines are injected[3]. We have recently confirmed Werner and Block's results indicating a discrepancy between the distribution of stable and radioactive iodine, when using very similar methods to estimate the distribution of iodinated amino-acids in human serum. Our extraction and chromatographic techniques differed from those of Mandl and Block[4] only in that the acidified serum was extracted three times with butanol and that the chromatogram was unidimensional and run in acid-butanol / 2 *N* acetic acid (1 : 1). We find that when

Fig. 2. Behaviour of some thiouracil derivatives on chromatograms stained for iodine by ceric–arsenite

the chromatogram of serum collected 48 hr. after a 100 μc. dose of iodine-131 is scanned for radioactivity little or no counts are recordable in the mono- or di-iodotyrosine positions, whereas when the same chromatograms are evaluated chemically for iodine by the ceric–arsenite reaction, iodotyrosines appear to be present in considerable quantity.

However, activation analysis by neutron bombardment in the Medical Research Council cyclotron to produce iodine-128 did not reveal any iodine in the region of the chromatogram corresponding to the positions of mono- and di-iodotyrosine. 5–10 ml. of normal serum had been run on paper from which the spots were cut. Evaluated by the fading with ceric–arsenite the chromatogram showed an iodine distribution of 20·5 per cent as iodide, 8 5 per cent as mono-, and 19·6 as di-iodotyrosine, whereas activation analysis produced iodine-128 from the iodide spot but less than 0·2 μgm. iodine/100 ml. serum from either of the apparent iodotyrosine spots (the thyronine region was not tested).

Further work suggests that the staining in the mono- and di-iodotyrosine regions of the chromatogram developed with ceric–arsenite may be due to the presence of thiourea. This substance had been added in μgm. quantities at all stages of the chemical processing in order to prevent any artefacts from the oxidation of iodide to iodine. In our chromatographic system thiourea, 2-thiouracil or methyl thiouracil has recently been found to run in the position of either mono- or di-iodotyrosine or between them, depending on the presence or absence of the iodotyrosines (Figs. 1 and 2); propylthiouracil runs in the position of the thyronines.

Careful study by direct colorimetry of the effect of thiourea on the time-course of the ceric–arsenite reaction shows that although there is some rapid initial fading this is virtually imperceptible when small (less than 100 μgm.) quantities of thiourea are used. Furthermore, the subsequent rate of fading is almost indistinguishable from that given by iodide, especially with small thiourea concentrations (Fig. 3).

From this we conclude that the apparent presence of mono- and di-iodotyrosine on chromatograms stained for iodine when prepared from normal human serum by our initial procedure may be an artefact due to added thiourea. Preliminary studies with activation analysis and an improved chromatographic technique have as yet failed to reveal detectable amounts of iodotyrosines in normal fasting human serum. Thus we cannot confirm the conclusions of Werner and Block, and we suggest that the apparent iodotyrosine staining which they find may have been

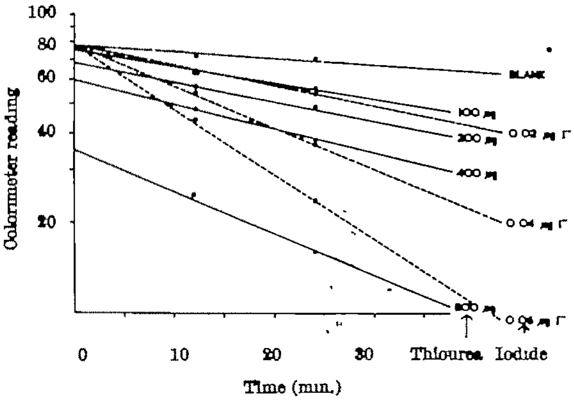

Fig. 3. Effect of thiourea on the time course of the ceric–arsenite reaction

an artefact due to thiouracil added during their extraction procedure.

Inhibition of Glucuronosyl Transferase by Progestational Agents from Serum of Pregnant Women

GLUCURONIDE conjugates are formed by the condensation of an alcohol or acid aglycone with uridine diphosphoglucuronic acid by the enzyme, glucuronosyl transferase[1]. A functional immaturity of this enzyme system and perhaps a deficiency of uridine diphosphoglucuronic acid has been observed in new-born animals[2]. Since indirect-reacting bilirubin is converted to bilirubin glucuronide by means of glucuronosyl transferase[3], Billing *et al.*[4] have suggested that physiological hyperbilirubinæmia of the new-born infant might be the result of a deficiency of this enzyme system. Recently, Lathe and Walker[5] reported inhibition of bilirubin conjugation in liver slices by serum of pregnant women. This communication reports studies aimed at identifying the inhibitor substances and assessing their importance in hyperbilirubinæmia of the new-born.

The effect of a final serum concentration of 14 per cent upon *o*-aminophenol conjugation by rat liver homogenate was studied using the method of Levvy and Storey[6]. The results (Fig. 1) indicated inhibition of 64·0 ± 21·8 per cent, 42·8 ± 22·5 per cent, and 48·2 ± 20·0 per cent by serum from pregnant women, immediately *post-partum* women, and new-born infants respectively, in contrast to inhibition of 1·3 ± 1·0 per cent and 26·8 ± 9·8 per cent by serum from adult males and adult non-pregnant females. Analyses of serial determinations indicate a gradual increase of *o*-aminophenol inhibition as term is approached, and a rapid fall after delivery.

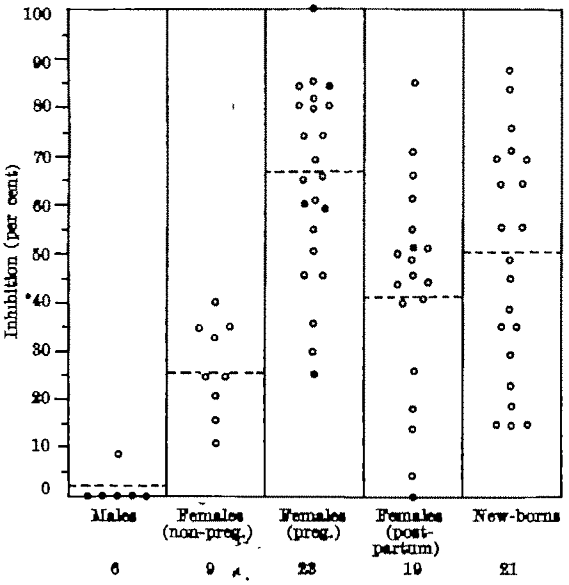

Fig. 1. Inhibition of *o*-aminophenol conjugation by various types of sera. Incubation mixture consisted of: 0·5 *M tris* buffer, pH 8·0, 0·1 ml.; 0·5 *M* magnesium chloride, 0·1 ml.; 1·1 × 10^{-2} *M* uridine diphosphoglucuronic acid, 0·1 ml.; 1·25 × 10^{-2} *M* *o*-aminophenol in 0·01 *M* ascorbic acid, 0·2 ml.; 10 per cent rat liver homogenate, 1·0 ml.; and serum, 0·22 ml. Incubation was carried out at 37° C. for 30 min.

The neutral lipids extracted from one litre of pooled serum from pregnant women were chromatographed on a silica column using gradient elution with benzene–ethyl acetate[7]. Four fractions were obtained which resulted in inhibition of *o*-aminophenol conjugation. The fraction showing most of the inhibitory activity contained a material which was chromatographed on propylene glycol-treated paper using toluene as developer; its migration corresponded to pregnanediol-3α,20α. On repeated recrystallization from ethanol, hexagonal prisms were obtained which showed a change in crystal structure at 210–220° C. and melted at 239·5–240° C. (Koffler micro-melting point). Authentic pregnanediol-3α,20α melted at 239·5–240° C. and a mixed melting point with the isolated crystals was 237·5–238·5° C. Infra-red spectra of the isolated material and pregnanediol are identical. On the basis of migration on paper and colour tests, other fractions are thought to contain *allo*-pregnanetriol and pregnanolone. All three compounds were found to inhibit conjugation *in vitro*.

Table 1. INHIBITION BY PROGESTINS OF PHENOLPHTHALEIN CONJUGATION BY RAT LIVER MICROSOMAL FRACTION

Compound	Final concentration (γ/ml.)	Inhibition (per cent)
17α-Ethyl-19-*nor*testosterone	0·8	50
Progesterone	6·0	50
Pregnanediol	4·0	30
17α-Ethinyl-19-*nor*testosterone	10·0	36
Androstenedione	8·0	27
17α-Ethyl-Δ^{5-10}-19-*nor*androstanediol	12·0	27
17α-Ethinyl-Δ^{5-10}-19-*nor*androstanediol	18·0	27
17α-Hydroxyprogesterone	16·0	15
17α-Methallyl-19-*nor*testosterone	32·0	50

Each flask contained microsomes equivalent to 0·3 gm. liver, 750γ phenolphthalein, 400γ uridine diphosphoglucuronic acid, 0·05 *M tris* buffer at pH 7·6, 0·012 *M* magnesium chloride, 0·015 *M* nicotinamide, 0·06 *M* potassium chloride, and is incubated at 37° C. for 30 min.

With these findings, it was decided next to test a series of progestational agents of physiological importance. 17α-ethyl-19-*nor*testosterone, progesterone, pregnanediol, 17α-hydroxyprogesterone, and 17α-methallyl-19-*nor*progesterone, 17α-ethinyl-19-*nor*testosterone, 17α-ethyl-Δ^{5-10}-19-*nor*androstanolone, 17α-ethinyl-Δ^{5-10}-19-*nor*androstanolone, 17α-hydroxyprogesterone, in order of decreasing effectiveness, were found to inhibit glucuronide formation as shown in Table 1.

With progesterone, inhibition was found using *o*-aminophenol, phenolphthalein, and bilirubin as substrates in both homogenates and microsomal fractions prepared from rat and guinea pig liver.

These observations may help to explain the jaundice which has been observed with prolonged administration of 17α-ethyl-19-*nor*testosterone and other steroids. High levels of progestins in maternal serum during pregnancy could play a part in the physiological hyperbilirubinæmia of the new-born.

This investigation was aided by grants from the Association for the Aid of Crippled Children, the U.S. Public Health Service (A-2222) and the Smith, Kline and French Foundation. We are indebted to Dr. E. G. Daskalakis for the authentic pregnanediol-$3\alpha,20\alpha$ and for help with the paper chromatography, and to Eva Gawronska Kot and Dorothy Poppish for technical assistance.

Plant-Growth Activity of α-Alkylphenylacetic Acids and 1,2-Benzo-1-*cyclo*alkene-3-carboxylic Acids

1,2,3,4-Tetrahydro-1-naphthoic acid (1,2-benzo-1-*cyclo*hexene-3-carboxylic acid) was found to have a high plant-growth activity. Its lower homologue, 1-indanocarboxylic acid (1,2-benzo-1-*cyclo*pentene-3-carboxylic acid) was reported later to be considerably active though less than the former[1]. In the homologous series of these two acids, the 1,2-benzo-1-*cyclo*alkene-3-carboxylic acids, the spatial relation of the carboxyl group to the ring system is influenced by the alicyclic ring structure. On the other hand, in the α-alkylphenylacetic acids, which may be regarded as the 'open forms' of the above acids, it is unnecessary to consider such an influence on the carboxyl group. In order to examine the effect on plant-growth activity of such a difference in the structure, we tested activities of these series of compounds in the pea straight-growth test.

In the α-alkylphenylacetic acids, the terminal of the alkyl chain is considered to lie preferably far from both the benzene ring and the carboxyl group in order to reduce steric repulsions to a minimum. The chain of *n*-alkanes has been shown by Bonham and his co-workers[3] to exist predominantly in all-*trans* configuration or in those which involve at least one *gauche* conformation. Therefore, the spatial relation of the carboxyl group to the ring may not change appreciably, even if the length of the side-chain changes. The carboxyl group in this series emerges considerably from the plane of the benzene ring. Fitting of the molecule to the site of action may, however, be interfered with when the molecular dimension increases due to elongation of the side-chain. The molecular dimensions of *n*-butylphenylacetic and *n*-amylphenylacetic acids, which are inactive, may be too large for fitting.

In the 1,2-benzo-1-*cyclo*alkene-3-carboxylic acids, increasing the carbon atoms in the alicyclic ring may not affect the molecular dimension so remarkably as in the above-mentioned series, because of their 'condensed ring structure'. The spatial configuration of the carboxyl group, on the other hand, may be affected considerably. Judged from the ultra-violet spectra and the molecular model, the carboxyl group of benzo*cyclo*butene- and indan-carboxylic acids takes a fixed conformation rising considerably from the plane of the benzene ring. The carboxyl of tetrahydro-naphthoic acid, which is more active than the two lower homologues, emerges from the ring plane more conspicuously when it takes a quasi-axial conformation, one of the two conformations inferable. The carboxyl group of benzo-*cyclo*heptene- and -*cyclo*octene-carboxylic acids, which are inactive, is presumed to be in a favourable equatorial conformation owing to hydrogen crowding of the ring and restriction of rotation of the group as suggested by Huisgen[4] concerning the conformation of 1,2-benzo-1-*cyclo*heptenyl- and -1-*cyclo*octenyl-3-methyltosylates.

Thus, the grade of activity of the two series of compounds may be explained by the steric circumstances of the molecule, as in the hydrogenated 1-naphthoic acids[5].

On the other hand, since the hydrophil–lipophil balance may not differ significantly between the corresponding members of the two series possessing the same number of carbon atoms, the abrupt drop

Table 1. PLANT-GROWTH ACTIVITY IN THE PEA STRAIGHT-GROWTH TEST*

of activity in each series from the C_{11}-acid to the C_{12}-acid may be understood by an increase in lipophilic nature beyond optimum, like toxicity in the homologous series of plasmoquin, bactericidal activity in *n*-alkanols, etc.[6]. Consequently, it cannot be decided whether this abrupt change is attributable to molecular form or hydrophil–lipophil-balance, though the plant-growth activity may be conditioned by the above two factors as suggested by Veldstra[7]. From this point of view it is hoped to obtain information about the activity of homologues of 1,4-dihydro-1-naphthoic acid, which are considered to have a higher chance of having their carboxyl group in the axial positions, owing to the smaller amount of hydrogen crowding.

Evidence for Multiple Nature of Cellulase of *Myrothecium verrucaria*

CONFLICTING views are held on the multiple nature of cellulase of *M. verrucaria*. Paper and column chromatography[1,2], zone electrophoresis[3] and electrophoresis-convection[4] of crude preparations of the cellulase indicated the multiple nature of this enzyme system. On the other hand, by fractionating the cellulase by precipitation techniques, Whitaker[5] obtained a preparation homogeneous in the ultracentrifuge and on electrophoresis, which exhibited all the activities tested of the crude enzyme concentrated in about the same ratios. He maintains that 1,4-β-linked oligo- and poly-glucosides are hydrolysed by one enzyme[6] which possibly forms stable complexes with metabolic products, thus giving rise to a number of components with cellulolytic activity[6,7].

In our investigations ion-exchange chromatography was used as a means to purify and/or fractionate the cellulase of *M. verrucaria*. 'Amberlite *IRC*–50' (120–200 mesh) was equilibrated with the buffer from which the cellulase was to be adsorbed. The cellulase was applied at the top of the column in a small volume of the buffer, and afterwards washed down with the same buffer. The column was operated at a speed of about 15 ml./cm.^{2} per hr. Elution was performed with buffers of increasing *p*H and/or molarity. The effluent was collected in fractions which were analysed for cellulolytic activity towards sodium carboxymethylcellulose.

Table 1

	Relative hydrolytic activity per mgm. nitrogen of the various fractions of cellulose towards					
	o-Nitrophenyl-β-D-glucoside	Cellohexaose	Soluble cellodextrin	Sodium carboxymethylcellulose	Swollen cellulose	Cellulose
Original enzyme	100	100	100	100	100	100
Fraction						
A	5	60	50	40	30	15
B	0	110	100	60	45	0
C	5	220	210	170	120	90
D	25	100	80	120	120	100
E	40	180	110	160	140	130
F	260	160	100	140	100	130

The cellulase used was a culture filtrate of *M verrucaria* grown on cellulose powder, which was concentrated about tenfold in a Bartholomew evaporator, afterwards dialysed against running tap-water (using collodion membranes), ultrafiltered, dialysed against distilled water and freeze-dried.

Cellulolytic activity towards sodium carboxymethylcellulose was measured by incubating 5 ml. of a 0·7 per cent solution of the substance (degree of substitution, 0·8) in buffer (*p*H 5·6) with 1 ml. enzyme solution for 1 hr. at 30° C. Reducing groups formed in 1 ml. of the incubation mixture were measured and expressed as 'mgm. glucose'. The amount of enzyme producing 0·4 'mgm. glucose' under these conditions was denoted 1 cellulase unit. The enzyme solutions tested were always diluted so as to contain 1 cellulase unit or less per ml.

The results of some preliminary experiments were as follows. No adsorption of cellulase was found from a buffer solution of *p*H 6·0 (0·048 *M*). Almost all the cellulase was adsorbed from a solution buffered at *p*H 4·2 (0·048 *M*), but the cellulase could be eluted only very incompletely.

At *p*H 5·2 (0·048 *M*) 70–75 per cent of the cellulase was adsorbed. Elution with buffers of higher *p*H and/or molarity gave recoveries of 80–90 per cent of the activity towards sodium carboxy-methylcellulose. On rechromatography under identical conditions of the cellulase which was not adsorbed, 90 per cent passed through the column.

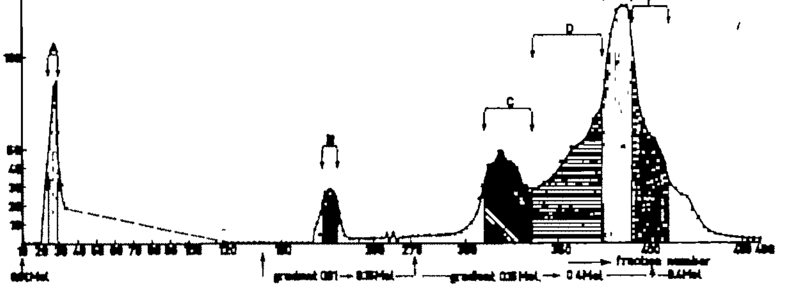

Fig. 1. Fractionation of 500 mgm. cellulase over a column of 'Amberlite *IRC*–50' (diam. 15 mm., length 73 mm.) equilibrated with phthalate buffer *p*H 5·2 (0·01 *M*) and eluted with the same buffer of increasing molarity. Fractions of 5 ml. were collected and the activity of each fraction towards sodium carboxy-methylcellulose was measured and expressed in cellulase units (see text)

The best results have been obtained so far with a column buffered with phthalate buffer pH 5·2 (0·01 *M*), eluting with the same buffer of increasing molarity. Fig. 1 shows the fractionation obtained. Peak *A* contains the cellulase not adsorbed. The fractions were combined as denoted in Fig. 1. Recovery of total activity applied to the column: for peak *A*, 6 per cent; *B*, 3·2 per cent; *C*, 10·1 per cent; *D*, 17·3 per cent; *E*, 17·7 per cent; *F*, 11·2 per cent; other fractions, 11·2 per cent. Total recovery 77 per cent.

Of the combined fractions *A–F* and of the original enzyme, dilutions were made containing the same activity towards sodium carboxy-methylcellulose (10 cellulose units/ml.) and of these the hydrolytic activity was measured towards the substrates: *o*-nitrophenyl-β-D-glucoside (niphegluc), cellohexaose, soluble cellodextrins, phosphoric acid swollen cellulose and α-cellulose. Protein concentrations were determined by the micro-Kjeldahl method. Table 1 shows the relative activities per mgm. nitrogen of the fractions when the activity of the original enzyme towards the substrate is given the value 100.

These results show that the fractions obtained by ion-exchange chromatography differ in the ratios of their activities towards a series of substrates of varying degree of polymerization. Especially fraction *B* is of great interest, as it does not hydrolyse niphegluc (nor cellobiose) nor α-cellulose, whereas its activity towards substrates of medium size (cellohexaose, cellodextrins) is as high as that of the original enzyme. Fraction *C* shows an increase in activity towards medium size substrates relative to the original enzyme. Most of the activity towards *o*-nitrophenyl-β-D-glucoside (and cellobiose) is present in fraction *F*. In our opinion these results strongly indicate the multiple nature of cellulase of *M. verrucaria*. Better resolution of the enzymes should be possible by refining the chromatography technique.

More details of this work, and further progress, will be published shortly.

We are indebted to Dr. P. Kooiman of the Laboratory of Technical Botany, Delft, who kindly provided the samples of cellohexaose and soluble cellodextrins.

PHYSIOLOGY

Effects of Ataractic Drugs on the Blood-Pressure and Heart-Rate of Dogs

THE assessment of the hæmodynamic effects of ataractic drugs, such as the phenothiazine derivatives, has, in the past, always been carried out in anæsthetized or curarized animals[1-4]. Since the action of the ataractic drug may modify, or be modified by, the effect of the anæsthetic or neuromuscular blocking agent, it has been difficult to assess whether the hæmodynamic changes observed have been due to the ataractic drug itself. It is therefore of interest to record a method of assessment which has been used for studying the effects produced by several phenothiazine derivatives in normal conscious dogs, and which has been shown to produce results which do not entirely agree with those obtained in anæsthetized animals.

Three healthy young dogs weighing 15–20 kgm. were surgically prepared with exteriorized carotid arteries and trained to lie quietly on a table while experimental procedures were being carried out. Standard limb lead electrocardiograms, and the blood-pressure obtained by puncture with a needle of the exteriorized carotid artery, were recorded simultaneously on a direct-writing multichannel recorder (Cambridge Instrument Co., Ltd.). The drugs were administered as a 1 per cent solution by intravenous injection through a previously inserted Mitchell needle at a dose-rate of 1 mgm. per kgm. body-weight. Recordings were taken before, during and after injection and every 5 min. thereafter until the maximum effect was observed (usually about 20 min. from the time of injection). Control experiments in which only saline was injected were also performed.

Seven phenothiazine derivatives were administered, in turn, to each dog:

(1), 2-chloro-10-(3-dimethylaminopropyl) phenothiazine hydrochloride (chlorpromazine hydrochloride)
(2), 10-(3-dimethylamino-2-methylpropyl) phenothiazine tartrate (trimeprazine tartrate)
(3), 10-(1-methyl-3-piperidylmethyl) phenothiazine (pecazine)
(4), 10-(2-dimethylaminopropyl) phenothiazine hydrochloride (promethazine hydrochloride)
(5), 10-(3-dimethylaminopropyl) phenothiazine hydrochloride (promazine hydrochloride)
(6), 10-(3-dimethylamino-2-methylpropyl)-2-methoxyphenothiazine hydrochloride (methotrimeprazine hydrochloride)
(7), 10-(3-dimethylamino-2-methylpropyl)-2-ethylphenothiazine hydrochloride (ethylisobutrazine in the United States, 6484 *R.P.*).

The results showed that all these drugs caused significant initial tachycardia (drugs 3, 5 and 7, $P < 0·001$; drugs 1 and 2, $P < 0·01$ and drugs 4 and 6, $P < 0·02$), but after 20 min. the changes in heart-rate were no longer significant. All the drugs appeared to produce an immediate effect on blood pressure, but on analysis it was shown that only drugs 1 and 7 caused significant hypotension ($P < 0·01$), while drug 3 brought about a significant rise in blood-pressure ($P < 0·01$). After 20 min. only drugs 1 and 7 were producing marked hypotension ($P < 0·001$), while drug 5 was causing a moderate decrease in blood-pressure ($P < 0·02$).

These results did not appear to agree with those which have been reported in anæsthetized animals and further experiments were performed to assess the effect of pentobarbitone anæsthesia on the response of blood-pressure and heart-rate to chlorpromazine. These experiments showed that the decrease in blood pressure from the pre-anæsthetic control-level, seen after the administration of chlorpromazine, was proportional to the depth of anæsthesia at the time of injection of this drug. Furthermore, the maximal effect on blood-pressure was obtained within 20 min. in the conscious dog, but under anæsthesia the maximum effect was not apparent until at least 30 min. after the injection of the drug. Anæsthesia also greatly reduced the immediate increase in heart-rate produced by chlorpromazine.

This investigation was carried out with the financial assistance of May and Baker, Ltd. The statistical

analyses were carried out by Dr. R. C. Campbell and Dr. J. T. Abrams.

Influence of the Ionic Strength of the Medium on the Anaphylactic Sensitization of Isolated Tissues *in vitro*

THE technique of *in vitro* sensitization of living tissues has permitted us to study various factors affecting the process of anaphylactic sensitization. The influence of the time of incubation, concentration of antibody, temperature, *p*H and composition of the medium has been already reported[1-4]. In this communication we present the results concerning the dependence of the sensitization on the ionic strength of the incubating antibody solution.

The experiments were performed with the guinea pig ileum, passively sensitized *in vitro* by incubation with rabbit, anti-egg albumin antibody, according to the technique previously described[2,3]. The antibody solution was prepared not in the usual Tyrode solution but in a medium almost free of electrolytes and made isotonic by the addition of dextrose. The composition of the medium was: dextrose 50 gm., sodium bicarbonate 42 mgm., distilled water 1 litre. Its *p*H, in equilibrium with air at 37° C., was approximately 7. Prior to sensitization the strips of intestine were washed with isotonic dextrose. During the period of incubation, the ionic concentration of the medium rose to, but never exceeded, $0 \cdot 002\mu$ (expressed as sodium chloride), presumably due to release of ions from the isolated intestine. When the influence of the ionic strength (μ) was investigated, varying amounts of sodium chloride, potassium chloride, calcium chloride, magnesium sulphate or potassium bromide were added. The salt concentration has been determined by conductivity measurements. In some experiments, dextrose was replaced by fructose, lactose, saccharose or arabinose.

The degree of sensitization was evaluated by the height of the contraction of the intestine produced in normal Tyrode solution after the addition of the specific antigen, and compared with that produced by a known dose of histamine.

Pieces of guinea pig intestine from the same animal were sensitized with the same amount of antibody in normal Tyrode solution and in dextrose medium. The intensity of the anaphylactic response of the intestine has been established as a function of the time of incubation in both media. It was found that the degree of sensitization was markedly increased in the medium with low electrolytic concentration. The results are shown in Fig. 1.

Dextrose can be replaced by fructose, saccharose, lactose or arabinose with identical results. This would suggest that the increased velocity of sensitization is related to the low concentration of electrolytes in the medium. To confirm this hypothesis we have studied the influence of various electrolytes at different concentrations, and in order to compare their respective effects, we have established, in every case, the time necessary to attain the same degree of sensitization. It was found that, for a given electrolyte, this time increased with its concentration. Furthermore, when different electrolytes were compared at the same ionic strength, their effect was found sensibly the same, regardless of their chemical nature. This result has been verified with sodium chloride, potassium chloride, calcium chloride, potassium bromide

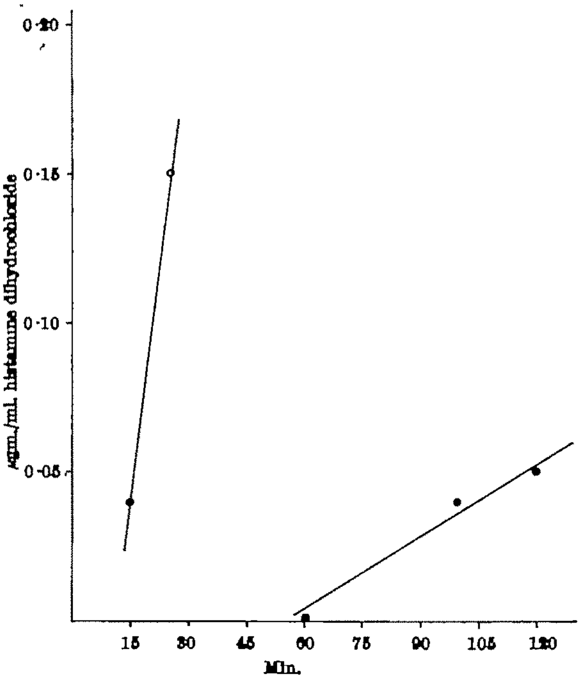

Fig. 1. Isolated guinea pig intestine sensitized passively *in vitro* at 37° C. with the same concentration of rabbit anti-egg albumin antibody (2 µgm. N/ml.). ●, sensitization in normal Tyrode solution ($\mu = 0 \cdot 15$); ○, sensitization in isotonic dextrose ($\mu = 0 \cdot 002$). Ordinate, height of the contractions expressed in histamine equivalent; abscissa, time of the incubation with the antibody

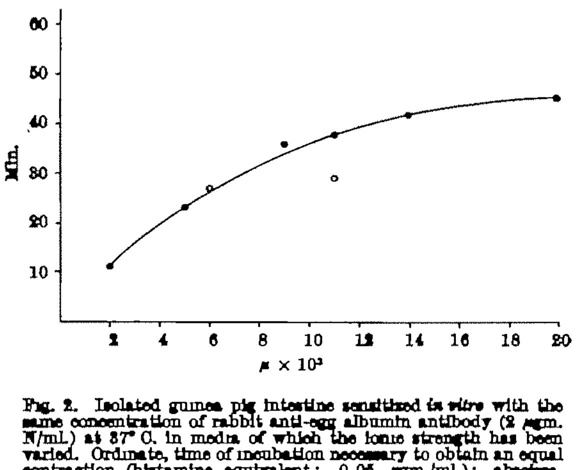

Fig. 2. Isolated guinea pig intestine sensitized *in vitro* with the same concentration of rabbit anti-egg albumin antibody (2 µgm. N/ml.) at 37° C. in media of which the ionic strength has been varied. Ordinate, time of incubation necessary to obtain an equal contraction (histamine equivalent: 0·05 µgm./ml.); abscissa, ionic strength of the incubating medium. In all experiments, the passive sensitization has been achieved in isotonic dextrose of which the ionic strength has been altered with sodium chloride (●), or magnesium sulphate (○)

and magnesium sulphate. A typical experiment is shown in Fig. 2.

The fact that the velocity is dependent on the ionic strength of the medium suggests that electrical interactions between globulin molecules or between antibody and cell play some part in the process of sensitization. Accordingly, it may be expected that modification of the *p*H would modify the rate of sensitization and the dependence of this rate on ionic strength. Preliminary experiments have shown that at low values of μ (of the order of 0·003) the sensitization process is highly dependent on the *p*H of the incubating solution.

Use of Diodone in Renal Studies in Sheep

Diodone (3,5-di-iodo-4-pyridone-N-acetic acid), shown by Elsom *et al.*[1], Landis *et al.*[2], and Smith *et al.*[3] to be an effective agent for the estimation of renal plasma flow and tubular function, has been used extensively in physiological studies. In 1945, Smith *et al.*[4] showed that *p*-aminohippuric acid was in some ways superior to diodone for these estimations in man because the urine and plasma blanks are small, and because diodone penetrates human red blood cells whereas *p*-aminohippuric acid does not. The red cells of dogs are permeable to both reagents.

Sheep, unlike the dog and man, normally excrete considerable quantities of hippuric acid in the urine[5]. The possibility that this endogenous hippuric acid may interfere with the estimation of *p*-aminohippuric acid is not remote when sheep are employed as experimental subjects.

A study was made of the permeability of the sheep's red blood cells to diodone by administering to six adult merino ewes, as an initial intravenous priming injection, 1·5 ml. 35 per cent diodone, and following this by a continuous intravenous infusion of 0·7 per cent diodone at the rate of 4 ml./min. over a period of 2 hr. At no time during or after the injection did the animals give any indication of being adversely affected by the diodone. Blood and urine (catheter) samples, taken at 30-min. intervals, were analysed for diodone[6] and *p*-aminohippuric acid[4].

Comparison of concentrations in the whole blood and the plasma indicated the passage of little, if any, diodone into the erythrocytes (Table 1). This was substantiated by the absence of diodone in the separated, saline-washed cells from three sheep subsequent to injection.

Analyses of the blood and urine samples collected during the periods in which diodone was administered failed to detect any reaction indicative of *p*-aminohippuric acid in any of the blood samples. A reaction of the same type as that given by *p*-aminohippuric acid, however, was always detectable in the urine; the concentration of this substance, which varied considerably with animals and with samples from the same animal, indicated excretions, which ranged from 0·2 mgm. to 1·1 mgm. for a 30-min. period. This is of the same order as that found by Smith *et al.*[4] to be excreted in similar circumstances by man and the dog. Thus the blanks arising from this substance are unlikely to interfere with the employment of *p*-aminohippuric acid for the determination of renal clearance tests in sheep.

It has also been established that the red cells of sheep are impermeable to circulating diodone, and thus differ from human red cells and from those of the dog.

Lack of Hæmatopoietic Potency of Liver of Mice fed on a Meat Diet

Recently, Adler[1] reported that mice fed on a diet composed of meat only develop an anæmia which is generally fatal but is cured by beef liver. Ilan, Kende and Guggenheim[2] have found that treatment of mice while subsisting on the meat diet with *para*-

* Calculated whole blood = Plasma value × hæmatocrit value (for plasma).

aminobenzoic acid, folic acid, vitamin B_{12}, liver extract, pyridoxine, iron, vitamin A, antibiotics (*per os*) or a combination of some of these substances neither prevents the anæmia nor the mortality nor does it improve growth. Some of these substances have, however, a slight effect in preventing anæmia. It could furthermore be shown that livers of mice suffering from 'meat anæmia' contained much more vitamin B_{12} than those of non-anæmic controls. It has been assumed that an essential hæmatopoietic factor, which is not vitamin B_{12}, folic acid or any other known hæmatopoietic factor, is absent from beef muscle; another possibility is the presence in beef muscle of an inhibitor of hæmatopoiesis.

We wish to report some further experiments conducted with the purpose of studying the effect of an addition of liver to the diet. 42 mice rendered anæmic by feeding the meat diet for 6 weeks were divided into 4 groups. One group served as control and continued on the meat diet. The diet of the three other groups consisted of three parts beef muscle and one part liver. The source of the liver of one of these groups was beef, that of the second, normal mice, and that of the third, anæmic mice. This dietary treatment lasted for 3 weeks. Table 1 presents figures for mortality, change in weight, erythrocytes and hæmoglobin. It shows that replacement of one of four parts of beef muscle by beef liver cured the anæmia completely and induced a considerable increase in body-weight. Liver of normal mice had a definite but smaller effect, and liver of anæmic mice resulted in no improvement.

Table 1. MORTALITY, WEIGHT CHANGES, RED BLOOD CELL COUNTS AND HÆMOGLOBIN OF ANÆMIC MICE FED ON LIVER INCORPORATED INTO A MEAT DIET

None, control (10)	Pre-treatment	—	14·6 ± 1·4	3·04 ± 0·13	6·6 ± 0·8
	3 weeks	7/13	13·4 ± 1·7	2·84 ± 0·54	3·5 ± 0·8
Beef liver (6)	Pre-treatment	—	17·0 ± 1·8	2·26 ± 0·10	5·8 ± 0·9
	3 weeks	2/6	21·0 ± 0·9	6·82 ± 0·23	15·8 ± 0·5
Normal mouse liver (13)	Pre-treatment	—	18·4 ± 0·6	3·14 ± 0·40	5·2 ± 0·54
	1 week	0/13	17·5 ± 0·6	3·65 ± 0·49	7·2 ± 1·22
	2 weeks	1/13	19·5 ± 0·7	4·42 ± 0·63	8·1 ± 1·04
	3 weeks	4/13	20·1 ± 0·8	5·39 ± 0·68	9·8 ± 1·17
Anæmic mouse liver (13)	Pre-treatment	—	16·2 ± 1·0	2·69 ± 0·37	5·6 ± 0·80
	1 week	2/13	16·0 ± 1·1	2·36 ± 0·23	4·4 ± 0·58
	2 weeks	9/13	15·8 ± 1·6	1·65 ± 0·23	2·8 ± 0·18
	3 weeks	11/13	16·8	1·42	2·3

These results are consistent with the theory that a hæmatopoietic factor is present in beef liver in higher concentration than in normal mice liver and is absent from liver of mice which had subsisted on beef muscle. The existence in liver of an anti-anæmic factor(s) other than vitamin B_{12}, folic acid and folinic acid has repeatedly been claimed[3].

Effect of Anti-Diuretic Hormone and Calcium on the Equivalent Pore Radius of Kidney Slices from *Necturus*

THE passive permeability of kidney slices may be expressed in terms of the equivalent pore radius. The present work is concerned with measurement of this parameter for kidney slices from the amphibian, *Necturus maculosus*, both under normal conditions, and as affected by the action of anti-diuretic hormone and calcium. Measurements have been made by the method of D. A. Goldstein and A. K. Solomon (private communication), which depends on the determination of the external concentration of permeant solute required to prevent water movement into or out of the cell at the instant of immersion in the medium. When the initial rate of change in volume of the cell is zero, the cell is in transient osmotic equilibrium with its environment. As Staverman[1] has pointed out, the concentrations required to produce transient osmotic equilibrium are higher for permeant solutes than for impermeant ones. Goldstein and Solomon have shown how these zero-time isotonic concentrations may be related to the equivalent pore radius.

Slices (0·2 mm. thick, 100–200 mgm. wet weight) from the kidneys of *Necturus* were weighed and immersed in a number of test solutions. Changes in the weight of the slice, which served as an index of cell volume change, were measured for 30 min. At 3–4-min. intervals, each slice was taken out of the solution, blotted, weighed and returned to the solution. Since the rate of change of weight was essentially constant during the first 5–10 min., an average during that period was determined and recorded as the per cent weight change per minute. All the bathing solutions contained sodium bicarbonate, 21 m*M*; dipotassium hydrogen phosphate, 0·6 m*M*; sodium dihydrogen phosphate, 2·4 m*M*; potassium chloride, 13 m*M*; magnesium sulphate, 1·2 m*M*; sodium sulphate, 0·6 m*M*; calcium chloride, 1 m*M* and glucose 5·5 m*M*, making a total of 78 mOsm./l. In addition, one of the following non-lipid-soluble non-electrolytes was added: raffinose, sucrose, mannitol, erythritol, glycerol or urea. The final total concentration ranged from 125 to 300 mOsm./l. *p*H was kept at 7·3 ± 0·1 by bubbling with 95 per cent oxygen and 5 per cent carbon dioxide. The experiments were performed at 18–20° C.

The zero-time rate of change of slice weight, $(dw/dt)_0$, is obtained by extrapolation. It is shown in Fig. 1 as a function of the concentration of probing molecule in the medium. Each point is the average of results obtained from 8–12 slices from 4–6 kidneys. It may be seen that $(dw/dt)_0$ for sucrose is zero at a concentration of 83 m*M*, as is also the case for raffinose and mannitol at the same concentration.

Table 1. C_{iso} AND σ FOR NON-LIPID-SOLUBLE NON-ELECTROLYTES IN KIDNEY SLICES

	No 'Pitressin'		'Pitressin'		Molecular radius* Å.
	C_{iso} (m*M*)	σ	C_{iso} (m*M*)	σ	
Urea	160 ± 10†	0·52	160	0·52	2·3
Glycerol	108 ± 4	0·77	128	0·65	2·9
Erythritol	93 ± 3	0·89	108	0·77	3·2
Mannitol	83 ± 4	1·0			4·0
Sucrose	83 ± 2	1·0	83	1·0	4·5
Raffinose	83 ± 3	1·0			6·0

* Molecular radii were determined on Stuart and Briegleb models, except raffinose, taken from viscosity measurements (ref. 8).

† Errors are standard errors of the mean.

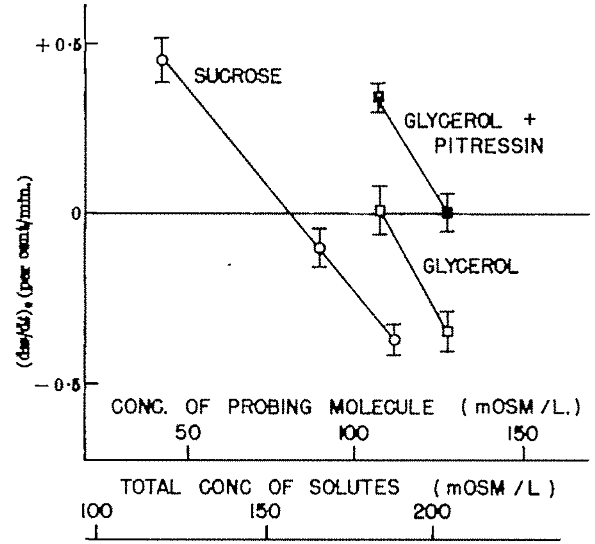

Fig. 1. Initial change in weight plotted as a function of the concentration of solute in the bathing solution. C_{iso} for sucrose may be seen to be 83 mOsm./l. compared with 108 for glycerol

Since we found the volume of distribution of mannitol to be the same as that of inulin in these kidney slices, it appears that all three solutes are confined to the extracellular phase during the course of our experiments. Consequently, the 83 m*M* concentration has been taken as the base line for comparison with experiments utilizing permeant solute. The zero time isotonic solution concentrations, C_{iso}, are given in Table 1. The determination of C_{iso} is equivalent to the determination of Staverman's reflexion coefficient, σ, also shown in Table 1. σ is given by the ratio (osmotic pressure due to permeant solute)/(osmotic pressure that would arise if solute were impermeant).

Goldstein and Solomon (private communication) have constructed a family of theoretical curves which relate (1 − σ) to the equivalent pore radius in the membrane and to the radius of the probing molecule. They applied these curves to their measurements of σ and obtained a figure of 4·2 Å., for the equivalent pore radius in human red cells, in agreement with the value of 3·5 Å. obtained by an independent method[5]; this agreement lends support to the use of σ to determine equivalent pore radii for such small pores. The curves given by Goldstein and Solomon (private communication) may also be applied to the data in Table 1. As shown in Fig. 2, an equivalent pore radius of 5·6 Å. fits our results. Although the slices are composed predominantly of proximal tubule cells, they contain also other cell types. Thus the figure of 5·6 Å. represents an average over all the types of cells that are encountered within the slice.

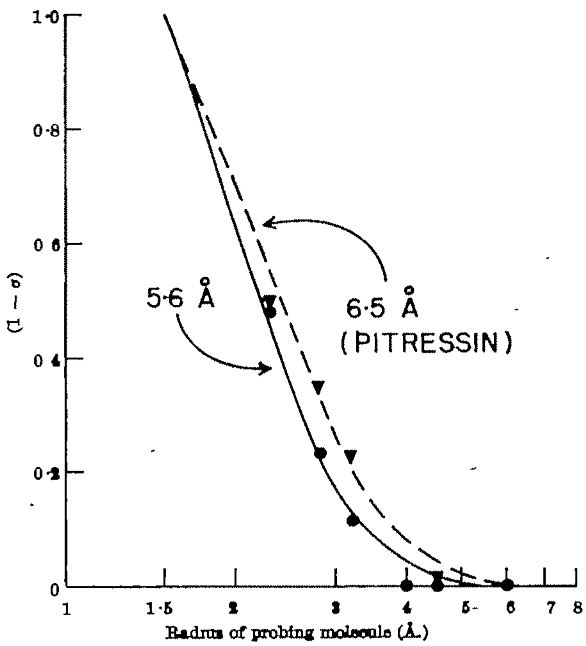

Fig. 2. (1 − σ), which is $[1 - \pi_{obs}/\pi_{theor.}]$ plotted as a function of the radius of the probing molecules. The circles represent our experimental values in normal animals and the triangles the results after injection of 'Pitressin'

The effect of anti-diuretic hormone ('Pitressin', Parke Davis and Co.) was examined in a group of experiments in which 10 pressor units of 'Pitressin' per animal were injected intraperitoneally $2\frac{1}{4}$–$3\frac{1}{4}$ hr. before the kidneys were taken out. As shown in Table 1, no change in C_{iso} for sucrose was observed; however, C_{iso} for erythritol and glycerol decreased significantly ($P = 0·01$). When these results are plotted in Fig. 2, it is seen that the equivalent pore radius is increased to 6·5 Å. Results compatible with this observation have previously been described by Ussing for toad skin[3], and by Sawyer and Hays *et al.*[5] for amphibian bladder.

Table 2. INHIBITION OF 'PITRESSIN' ACTION BY CALCIUM IN *Necturus* KIDNEY SLICES

Calcium (m*M*)	Initial rate of weight change in isotonic glycerol* (per cent/min.) 1	5	10
No 'Pitressin'	0·01 ± 0·07	0·00 ± 0·04	0·01 ± 0·06
'Pitressin'	0·34 ± 0·04	0·17 ± 0·04	−0·03 ± 0·06
'Pitressin' induced effect	0·33 ± 0·08	0·17 ± 0·06	−0·04 ± 0·08
P of induced effect	< 0·01	0·02	> 0·6

* The solutions were maintained isotonic by substitution of calcium chloride for sodium bicarbonate. The glycerol concentration was 108 mOsm./l. The osmolarities of the solutions were checked by freezing-point depression.

The absence of calcium is known to cause cell swelling, as shown by Fukuda[6] in *Anthocidaris* eggs, and by Bozler[7] in muscle. Consequently, it seemed desirable to examine the influence of calcium on our preparation. An increase of calcium from the normal value of 1 m*M* up to 10 m*M* had no detectable effect on $(dw/dt)_0$ when the cells were immersed in sucrose solutions. On the other hand, removal of calcium from the medium produced a sharp increase in weight, the tissue becoming permeable to sucrose (molecular radius 4·5 Å.), though remaining impermeable to raffinose (molecular radius 6·0 Å.). It may be inferred that the calcium content of the membrane exercises a delicate control over the equivalent pore radius. Consequently, a set of experiments was carried out to see whether excess calcium might inhibit the action of anti-diuretic hormone. The results shown in Table 2 indicate that this is indeed the case. When the slices are immersed in isotonic glycerol, 5 m*M* calcium reduces the effect of 'Pitressin' to half and 10 m*M* calcium suppresses it. A similar effect has been observed when the slices are immersed in isotonic erythritol, 10 m*M* calcium completely inhibiting the 'Pitressin' effect. These results suggest that the action of anti-diuretic hormone on membrane permeability may be due to an interaction with membrane calcium.

This work was supported in part by grants from the Life Insurance Medical Research Fund and the National Science Foundation.

Note added in proof. Since this communication was submitted, we have seen a paper by P. J. Bentley (*J. Endocrin.*, 18, 327; 1959), who observed a similar interaction between calcium and 'Pitressin' on toad bladder.

HÆMATOLOGY

MNSs Gene Frequencies in English Blood Donors

ESTIMATES of the MNSs gene frequencies in the English population have been based hitherto on the results of tests with anti-M, -N and -S only[1,2]. Recently, a supply of the very rare anti-s was made available through the kindness of Dr. J. O'Riordan of Dublin[3], and a random series of 1,000 Sutton blood donors was tested with all four antisera. The samples were also tested with anti-Mia, -Vw and -Mg. All were negative with the last two antisera, but one donor was found to be *Ms*/*Ns*, Mi(a +) Vw−, and a study of her family showed *Mi*a to be travelling with *Ns*. The results of the major grouping tests are given in Table 1.

Table 1. SAMPLES FROM 1,000 UNSELECTED SUTTON BLOOD DONORS TESTED WITH ANTI-M, -N, -S and -s

Reactions with anti -M	-N	-S	-s	Number
+	−	+	−	57
+	−	+	+	140
+	−	−	+	101
+	+	+	−	39
+	+	+	+	224
+	+	−	+	226
−	+	+	−	3
−	+	+	+	54
−	+	−	+	156
			Total	1,000

Table 2. PERCENTAGE FREQUENCIES OF THE MNSs GENES IN ENGLISH PEOPLE

	Sutton series, 1959 Calculations based on the use of Anti-M,-N,-S-s	Anti-M,-N,-S	Race and Sanger (ref. 1) 1950	Ikin *et al.* (ref. 2) 1952
MS	23·11 ± 1·022	23·58 ± 1·116	24·72	24·02
Ms	30·90 ± 1·102	30·67 ± 1·185	28·31	29·71
NS	7·09 ± 0·678	6·89 ± 0·807	8·02	5·64
Ns	38·90 ± 1·155	38·86 ± 1·233	38·95	40·63
No. tested	1,000		1,419	1,166

Gene frequencies have been calculated by the method of maximum likelihood estimation, and are presented in Table 2. They have also been calculated from the same data, assuming the use of anti-M, -N and -S only; these results are included in Table 2 for comparison along with those of Race and Sanger[1], and of Ikin *et al.*[2], whose tests were in fact made with the three sera only. The calculated gene frequencies, when recombined, give expected figures for the 9 phenotype classes which fit very closely with those observed ($\chi^2 = 3{\cdot}64945$ for 4 d.f.)

I am indebted to Dr. J. H. Edwards of the Medical Research Council Population Genetics Research Unit, Oxford, for the statistical treatment. He has estimated from these results that tests on 800 samples with all four antisera may be expected, on average, to yield as much information as tests on 1,000 samples with the three antisera more readily available.

Chemical Constitution of the Red Blood Cell Membrane

SOME authors[1–6] claim that the red blood cell membrane is a continuous lipoid. Others[7–10] do not accept this. They assert that the membrane consists of a protein skeleton with lipoid molecules in the hollows of the protein skeleton.

The work reported here aims at settling this with the help of the Sanger dinitrofluorobenzoic acid method for amino end-group determination[11].

Red cells freed from native protein and its fraction were used. Fractionation was as follows: to 10 ml. red cell suspension 20 ml. physiological salt solution and 10 ml. ether were added. This was shaken for 5 min. and then centrifuged. Three phases resulted: the central layer (the stroma) was solid; the upper ether phase contained lipoid; the lower solution contained hæmoglobin. The extraction was repeated five times. We combined the fraction obtained in the course of the extractions. The stroma and the watery solution from ether were dried and the ether solution evaporated. Thus we obtained ether-soluble lipoid- and hæmoglobin-free stroma, ether hæmolysate and such lipoid fraction as contained any ether-soluble fat-like matter.

Since the alcoholic solution of dinitrofluorobenzoic acid causes hæmolysis on native red cells, the method had to be modified. The reactions were performed with native red cells and aqueous solution, with physiological salt of dinitrofluorobenzoic acid at *p*H 8·0 (0·15 *M* HCO_3–CO_3), at 37° C. by slight stirring for 60 min. Hydrolysis of the products was effected with 6 *N* hydrochloric acid at 105° C. (6 hr.). Analysis of purified dinitrophenyl derivatives was performed with paper chromatography[12].

The chromatogram of native red cell and of its three fractions is illustrated in Fig. 1.

Each substance was identified by its mobility and by the application of model compounds.

On the surface of the native red cell[9] two amino-acids, arginine and serine amino end-groups, are to be found. Serine can be derived both from stromatin-proteins and from cephalin; consequently its presence is not conclusive. The arginine, however, is exclusively of protein origin, therefore the stroma-proteins are not likely to be encircled by coherent lipoid membrane. This fact is confirmed by Block and Bollding[13], who

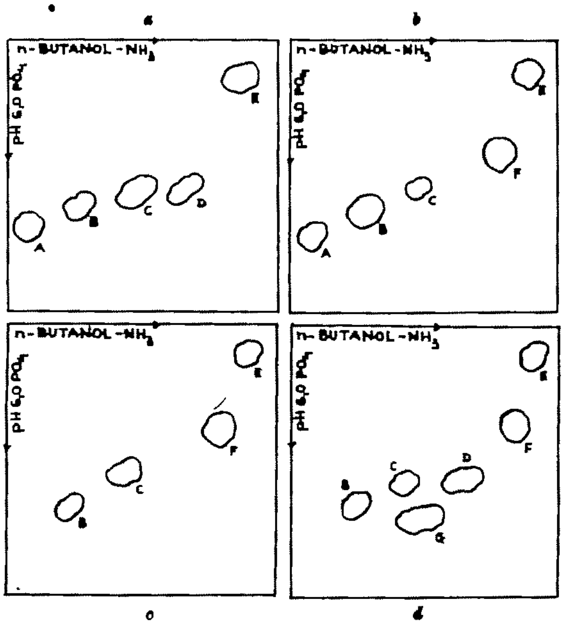

Fig. 1. *a*, Native red cells. *A*, DNP-arginine; *B*, DNP-serine; *C*, unknown amine; *D*, unknown amine; *E*, DNP-NH$_2$. *b*, Lipid-free stroma; *F*, DNP-colamin. *c*, Lipid extraction. *d*, Hæmolysate; *G*, DNP-valine

find that the arginine content of stroma-protein is very high. After the removal of a greater part of lipoids by ether from the stroma obtained further end-groups originating from amino-acid could not be observed. The fact that serine is to be found in the stroma, too, confirms its protein or cephalin origin, which in greater part is attached to protein, although it probably occurs in the form of lipoprotein. The latter is confirmed also by the fact that colamin can be found in the stroma in great quantities, which can be isolated in the form of dinitrophenyl-colamin. In the lipoid fraction removed from the red cell by ether, serine and an unknown amino compound were found (Fig. 1c).

The possibility arose that the dinitrofluorobenzoic acid did not react on the surface of the red cell only but also in its interior. Our experiments have shown that this is not the case, because in the hæmolysate of typical hæmoglobin origin[11] 2 mol. valine end-group appeared; in the case of the native red cell this product could not be found.

PATHOLOGY

High-Energy Bound Phosphate and Diabetes Mellitus

THE problem of whether oxidative phosphorylation is impaired in diabetes mellitus or not remains obscure. Cutolo and Siliprandi[1] and Sacks[2] demonstrated a decrease in high-energy bound phosphate content in alloxan-diabetic rat liver. Vester and Stadie[3] found diminished oxidative phosphorylation in depancreatized cat liver mitochondria but not in alloxan-diabetic rat liver mitochondria. Parks *et al.*[4] also failed to find an abnormality in alloxan-diabetic rat liver mitochondria. Goranson and Erulkar[5] found uncoupling of oxidative phosphorylation in the heart muscle of alloxan-diabetic rats, but Peterson and his collaborators[6] reported that the high-energy bound phosphate content of skeletal muscle was in the normal range.

In order to see whether the formation of high-energy bound phosphate is disturbed in diabetic patients, we determined the blood high-energy bound phosphate in 65 diabetic patients and 63 non-diabetic control subjects. The blood high-energy bound phosphate content in the overnight fasting state was determined as 10 min. hydrolysed phosphorus by the method described elsewhere[7]. The values obtained by the method showed a fair agreement with those obtained by the method of Wolff and Paysant[8]. The diabetic patients studied were non-ketotic. In patients treated with insulin, blood specimens were obtained after the omission of regular insulin for 24 hr.

The mean 10-min. phosphorus in blood level was $3 \cdot 4 \pm 0 \cdot 09$ mgm./100 ml. for the diabetic group and $3 \cdot 5 \pm 0 \cdot 11$ mgm./100 ml. for the control group and there was no significant difference statistically ($P > 0 \cdot 10$). The mean 10 min. phosphorus content of blood cells was $7 \cdot 7 \pm 0 \cdot 17\gamma \times 10^{-9}$ per red cell for the diabetic group and $7 \cdot 8 \pm 0 \cdot 07\gamma \times 10^{-9}$ per red cell for the non-diabetic group. Therefore, the fasting blood high-energy bound phosphate content of diabetic patients was not different from that of non-diabetic control subjects.

Our previous work showed, however, that the injection of adrenaline (0·5 mgm.)[7] or cortisone (25 mgm.)[9] depressed the level of blood 10 min. phosphorus to a greater extent in diabetic patients than in non-diabetic subjects. The increase in blood 10 min. phosphorus produced by the subcutaneous injection of insulin (5 units)[9], by the oral administration of 25 gm. of butter[10] or by the oral administration of 1 gm. of carbutamide[11] was significantly less in diabetic patients than in non-diabetics. No significant difference between diabetic patients and non-diabetic subjects was found in the changes of blood 10 min. phosphorus-level after the oral ingestion of 50 gm. of glucose[12], after the intramuscular injection of glucuronic acid (1,000 mgm.)[13] or after the oral administration of phenethylbiguanide (100 mgm.)[11]. Similar results were obtained in the study on alloxan-diabetic rabbit liver 7 min. phosphorus, that is, there was no significant difference in the liver 7 min. phosphorus in the post-absorptive state between diabetic rabbits and normal rabbits, but the change after adrenaline administration (0·01 mgm./kgm.) was significantly greater and the change after insulin (1·5 units/kgm.) was significantly less in the diabetic rabbit groups than in the normal group[14].

We feel that diabetic patients have a slight disturbance in high-energy bound phosphate formation which becomes manifest after the administration of adrenaline, cortisone, insulin, etc.

Recovery of Leukæmogenic Agent from Non-Leukæmic Tissues of Thymectomized Mice

It has been shown by Gross and others[1] that filtrates of leukæmic tissues are leukæmogenic following injection into new-born mice of a low-leukæmic strain, and that total thymectomy prevents the development of lymphocytic leukæmia in inoculated mice[2]. On the other hand, normal thymuses grafted to inoculated thymectomized hosts as late as 6 months after thymectomy develop lymphocytic neoplasms[3]. It follows, therefore, that a leukæmogenic agent might be recoverable from the tissues of inoculated mice up to 6 months or more after thymectomy.

Six-months old *C3Hf*/*Gs* mice, which had received an intraperitoneal injection of passage *A* filtrate (a potent leukæmogenic filtrate) at or soon after birth and had been thymectomized at 3–4 weeks of age, were killed, and extracts were prepared from their spleens or brains. Microscopic examination of these organs did not reveal any leukæmic cells or any other abnormality. Some of the spleen cells were transplanted to normal adult *C3Hf*/*Gs* mice, but these remained free from leukæmia during a total period of observation of 8–9 months. The spleen and brain extracts were inoculated intraperitoneally into new-born *C3Hf*/*Gs* mice, which then received no further treatment. As can be seen in Table 1, 60–80 per cent of the mice in the experimental group developed leukæmia as early as 3 months after birth. No leukæmia developed in 13 control mice inoculated with brain and spleen extracts prepared from untreated 6-month-old *C3Hf*/*Gs* mice.

Extracts from non-leukæmic tissues of inoculated thymectomized hosts were passaged through successive generations of thymectomized mice and finally into non-thymectomized mice. Leukæmias are already appearing in the group with intact thymuses, suggesting that: (1) multiplication of the leukæmic agent has taken place each time during transfer through thymectomized hosts; (2) the thymus is not a necessary site for replication of the agent since in the last two generations of thymectomized hosts the material was injected after thymectomy. These results will be published in full detail when the results are complete.

Effect of a Primary Tuberculous Infection on the Resistance of Male and Female Mice to Ectromelia

A TUBERCULOUS infection or vaccination with *BCG* has been shown to raise the resistance of mice and guinea pigs not only to a challenge with mycobacteria but also to secondary infections caused by other species of bacteria. This latter, non-specific type of immunity has been demonstrated against infection with *Brucella abortus*[1], *Bacillus anthracis* and *Brucella suis*[2], *Staphylococcus aureus*[3], *Pasteurella pestis*[4] and *Salmonella enteritidis*[5]. The present work was undertaken to see whether a primary tuberculous infection also increased the resistance of mice to virus infections, using in the first instance ectromelia (mouse pox) as the test virus.

Male and female mice, strain *VS*, aged 7–9 weeks (weight 18–20 gm.) were each divided into two groups.

Table 1

Experiment No.	Tuberculous mice				Normal mice			
	Male		Female		Male		Female	
	Survivors* No. per group	Percentage of survivors	Survivors* No. per group	Percentage of survivors	Survivors* No. per group	Percentage of survivors	Survivors* No. per group	Percentage of survivors
1	8/20	40	11/19(1)†	58	4/30	13	5/10	50
2	11/30	37	12/28(2)†	43	5/30	17	15/29(1)†	52
3	13/56(4)†	23	9/56(4)†	16	2/59(1)†	3	17/55(5)†	31
Total	32/106	30	32/103	31	11/119	9	37/94	39

Mice inoculated intraperitoneally with ectromelia (experiments 1 and 2, 10 *LD*50; experiment 3, 30 *LD*50) 3 weeks after infection with *Myco. tuberculosis*.

* Seventeen days after infection with ectromelia.

† Bracketed figures indicate number of mice which died without typical ectromelia or with severe tuberculosis and were excluded from group.

Probability that difference between survivor ratios for tuberculous and normal males occurred by chance $< 0·001$ ($\chi^2 = 14·6$).

Probability that difference between survivor ratios for normal males and normal females occurred by chance $< 0·001$ ($\chi^2 = 25·6$).

Probability that difference between survivor ratios for tuberculous males and normal females occurred by chance $> 0·2$ ($\chi^2 = 1·47$).

One group of male and one of female mice were inoculated intravenously with 0·0065 mgm. *Mycobacterium tuberculosis* (virulent human strain, *H37Rv*) in order to produce a chronic stable type of pulmonary tuberculosis[4]. One group of each sex was left uninfected. Three weeks later, when the infected mice showed small tuberculous lesions in the lungs, all groups were inoculated intraperitoneally with a suspension of ectromelia. In the first two experiments the virus suspension contained approximately 10 *LD*50 per inoculated dose and in the third experiment 30 *LD*50 (determined with weanling mice aged 3–4 weeks). Subsequent deaths were recorded daily and the cause of death confirmed at autopsy. The few mice which died without typical lesions of ectromelia or with lesions of tuberculosis sufficiently severe to account for death were excluded from an experiment. The results of three such experiments are shown in Table 1. In all the experiments the resistance to ectromelia of the normal male mice, as indicated by the proportion of survivors, was consistently less than that of the male mice with tuberculosis. The resistance to ectromelia of normal female mice, initially higher than that of normal male mice, was not significantly influenced by a primary tuberculous infection and was approximately equal to that of the male mice with tuberculosis. The lower resistance of the normal males compared with the females may not apply to mice of all strains and ages. We have some evidence that the resistance of normal weanling mice (aged 3–4 weeks) of strain *VS* is about the same in males and females.

Under the conditions of these experiments, tuberculosis increases the resistance of adult male mice to the lethal effects of ectromelia, a typical pox virus. Although tuberculosis can increase the resistance of animals to secondary infections caused by other species of bacteria, this is the first time it has been observed with a secondary virus infection. Nevertheless it is not known whether this increased resistance to a virus infection results from the same non-specific immune processes which operate against the bacterial injections.

RADIOBIOLOGY

Comparison of Iodine-124 and Iodine-131 in Inhibition of Goitrogenesis in the Rat

Phillips[1] has suggested that iodine-124 might prove more effective than iodine-131 in the treatment of cancer of the thyroid, largely because the greater energy of its β-rays should increase the amount of radiation administered from areas of functioning tumour to adjacent foci that do not take up iodine. We were therefore interested to compare experimentally the damaging effect on the thyroid of the two isotopes. The method used was that of Doniach and Logothetopoulos[2], who showed that radiation damage to the thyroid of rats may be revealed by their loss of ability to produce goitres in response to a 10-day course of propylthiouracil when challenged 3–4 months after a single dose of iodine-131. Marked inhibition of goitrogenesis resulted from an intraperitoneal injection of 30 μc. of iodine-131. This dose gives a mean of about 12,000 rads to the rat thyroid with the very large range of about 2,000–24,000 rads, due to uneven uptake and distribution of iodine in the thyroid and loss of β-radiation from the gland periphery. It was found that the dose of external X-irradiation to the rat's thyroid necessary to inhibit the goitrogenic response to a degree equivalent to 30 μc. of iodine-131 was only 1,000 rads[3]. It is likely that part of the greater effectiveness of external X-irradiation over iodine-131 in terms of dosage is a reflexion of the uneven uptake of iodine and consequent comparative escape from iodine-131 radiation of less-actively functioning areas of thyroid. We thought that the radiation dose of iodine-124 necessary to inhibit goitrogenesis would be less than that of iodine-131 because its more penetrating radiation might even out the dosage throughout the thyroid gland, following Phillips's[1] argument with regard to thyroid cancer.

The iodine was prepared on the Medical Research Council cyclotron at Hammersmith Hospital by bombarding antimony with α-particles of about 18 MeV. A chemical separation of the iodine produced a specimen of high specific activity (1 mc./μgm.); the iodine-124 was, however, contaminated with other radioisotopes of iodine inevitably formed in the alpha bombardment of natural antimony. These are iodine-123 (half-life 13 hr.), iodine-126 (13 days) and iodine-125 (60 days). The extent of the contamination was estimated by following a sample of the mixture in a re-entrant ionization chamber. This chamber had been calibrated with several known isotopes, and its response was found to be linear with specific γ-ray emission if radiations below about 100 keV. are ignored. At the time of administration it is estimated that the response of the chamber to the different isotopes was in the proportions iodine-123 : iodine-124 : iodine-126 = 1·0 : 2·0 : 0·17. The proportions in terms of microcuries can be found by dividing these figures by the appropriate specific γ-ray emissions. There is some uncertainty about the specific γ-ray emission of iodine-124 (refs. 4–7); the figures for the administered quantities quoted in the table assume a value of 6·5 r./mc. hr. at 1 cm., the contribution from the 30-keV. X-rays being ignored. The estimated quantity of iodine-124 administered is inversely proportional to the figure assumed. The amount of iodine-125 present was not directly determined, but experience with previous samples indicates that it was present to the extent of only a few microcuries per 100 microcuries of iodine-124.

Table 1

Group (number of rats per group in brackets)	Thyroid weight in mgm. ± *S.D.* of mean	Percentage inhibition of goitrogenesis
Controls (11)	23·6 ± 0·8	—
Methylthiouracil (11)	48·9 ± 3·1	0
10·1 μc. iodine-131 followed by methylthiouracil (12)	44·7 ± 1·3	20
29·5 μc. iodine-131 followed by methylthiouracil (12)	34·8 ± 1·1	60
21 μc. iodine-124 followed by methylthiouracil (11)	45·3 ± 2·9	20
37 μc. iodine-124 followed by methylthiouracil (12)	40·0 ± 1·5	40
53 μc. iodine-124 followed by methylthiouracil (11)	35·0 ± 2·2	60
126 μc. iodine-124 followed by methylthiouracil (11)	27·7 ± 1·7	88
222 μc. iodine-124 followed by methylthiouracil (12)	24·7 ± 0·8	100

Thyroid weights of rats after 16 days on 0·1 per cent methylthiouracil in the drinking water, started 104 days after intraperitoneal injection of various doses of iodine-124 or iodine-131. Percentage inhibition of goitrogenesis is calculated on the assumption of 25 mgm. for weight of the untreated thyroid and 50 mgm. for the weight of methylthiouracil goitre in the absence of radiation inhibition.

105 male pen-inbred rats of the hooded Lister strain were divided into 9 groups, 11 or 12 per group. At the age of 8–9 months the rats in 7 groups were injected intraperitoneally with carrier-free iodine-131 or iodine-124 in 1 ml. water in the dose-range shown in Table 1. 104 days later the treated animals and 1 non-radiated group were put on methylthiouracil in the drinking water, 1 gm. per l., and killed after sixteen days of this goitrogenic regime together with the remaining group of non-irradiated, non-thiouracil-treated controls. There were two deaths among the 105 rats during the experiment. The average thyroid weight of the controls was 23·6 mgm., and that of the thiouracil but non-radioactive iodine-treated was 48·9 mgm. Thus the goitrogenic regime had doubled the thyroid weight. It is seen in Table 1 that 29·5 μc. iodine-131 significantly inhibited the goitrogenic response, the thyroid weight being 34·8 mgm. However, 10·1 μc. iodine-131 showed little effect, the thyroid weight being 44·7 mgm. The dose of iodine-124 equivalent to 29·5 μc. iodine-131 in inhibition of goitrogenesis was 53 μc. thyroid weight 35·0 mgm. The degrees of inhibition of goitrogenesis produced by the various doses of radioactive iodine may be expressed as percentages, as shown in Table 1 where the control thyroid weight is regarded as 25·0 mgm., and the goitrogen treated as 50 mgm. 29·5 μc. iodine-131 and 53 μc. iodine-124 each showed a 60 per cent inhibition.

To interpret this equivalence in terms of radiation dose is not easy. The dimensions of the rat thyroid are comparable with the ranges of β-particles, and calculations of radiation dose are therefore very dependent on the precise geometry of the gland and the exact ranges of the particles. If the biological half-life of iodine in the gland is taken as 100 hr., and the gland is assumed to consist of two cylinders 5 mm. long and 2 mm. in diameter, an approximate calculation shows that about 2·5 μc. of iodine-124 will give the same average radiation dose to the gland as 1 μc. of iodine-131. Our experimental result of 1·8–1 suggests that rather less than this amount of iodine-124 is required in order to produce equivalent damage. The comparison is approximate, particularly because of the uncertainty in the value of the specific γ-ray emission of iodine-124. It is, however, considered very fully in recent work by Christine M. Matthews and J. F. Fowler[8].

Our thanks are due to the cyclotron staff here for preparation of the iodine-124.

Behaviour of Radioactive Griseofulvin in Skin

THE present clinical and laboratory success of griseofulvin in the treatment of superficial fungal infection has prompted investigation into the sites of concentration of this material in an effort to clarify its effects. Preliminary work with spectrophotometry suggested that griseofulvin accumulated, at least for short periods, in the skin. Since this tissue is also the site of the primary infection, I confined my studies to the localization of the agent in that organ, using radioactive griseofulvin the presence of which could be identified by radioassay and autoradiography.

Two investigations were made using griseofulvin–chlorine-36 of specific activity 6·7 μc. per gm. In the first part 2 normal rats were fed by tube 100 mgm./kgm. of radioactive griseofulvin on three successive days. The rats were killed 4 and 7 hr. respectively after the last doses, and radioassay and spectrophotometric analyses were carried out on skin samples. Other skin specimens were used for autoradiography with 10- and 15-μ sections exposed to Kodak *A.R.* 10 and *A.R.* 50 autoradiographic film after eosin staining. Parallel control experiments were employed with one rat receiving no therapy and three rats to which had been given DL-cystine–sulphur-35 (specific activity

31 µc./m.mole) in respective doses of 100, 10 and 1 µc. per 100 gm. weight on three successive days before killing.

In the second experiment a 10 per cent preparation of the radioactive griseofulvin was applied to an area of the skin surface of 2 normal patients and to the tinea lesions of 8 infected human patients. Geiger counting was done after application and 8 hr. later immediately prior to skin biopsy following cleansing of the area with spirit. Biopsies were examined by autoradiography.

In the first experiment with normal rats autoradiographs showed that in the griseofulvin-treated animals sites of radioactivity were limited almost entirely to the hair follicles; some accumulation was seen in the stratum corneum adjacent to the follicular openings. Of the hair follicles, only those in the anagen phase of the growth-cycle contained radioactive grains, and of these, only 1 in 10. Grains accumulated in the suprabulbar region initially, and with the growth of hair keratin, were gradually carried toward the surface, which they reached in three days. Three separate bands could be seen, interrupted by zones without activity, apparently representing the three separate doses of radioactive material given. No grains were observed in the bulb of the hair. The greater suprabulbar accumulation of radioactivity was seen in the rat killed 7 hr. after the last dose of griseofulvin.

In the rats to which DL-cystine–sulphur-35 had been given almost all the hair follicles except those in the telogen phase were found to contain radioactivity. Grain concentration was dense, in contrast to that seen in the griseofulvin-treated rats. Radioactive material had accumulated in the suprabulbar portion of the follicle, the keratogenous zone, and throughout the length of the hair shaft, suggesting that the radioactive cystine had been fully incorporated into the keratin. The stratum corneum also contained a diffuse and moderate concentration of radioactivity.

Assays based on content of radioactive chloride and radioactive griseofulvin (Table 1) agree closely, indicating that the griseofulvin–chlorine-36 molecule remained relatively intact during its 3-day sojourn in the skin examined here. One of the sets of figures obtained from spectrophotometric analysis corroborates this. Both results also suggest an increase in concentration of griseofulvin in the skin 4–8 hr. after dosage. Comparison of these figures with those obtained by calculation of the theoretical skin content if distribution were equal throughout all tissues suggests that the concentration of griseofulvin actually in skin is approximately 10 times that expected.

Table 1

	Treatment administered						
	Griseofulvin–^{36}Cl		DL-Cystine–^{35}S			Nil	
	1 (killed 68 hr.)	2 (killed 71 hr.)	3	4	5	6	7
Total dose of radioactivity (µc./100 gm. rat)	0·2	0·2	300	30	3	0	0
Radioactivity of skin (% of dose)	0·004	0·02	0·4	0·2	0·23	0	0
Griseofulvin assay							
Spectrophotometry (% of dose)	0·023	0·027					
Radioassay* (% of dose)	0·004	0·021					
Expected content based on even tissue distribution (% of dose)		0·0027					

* Assuming all chlorine-36 remains in griseofulvin.

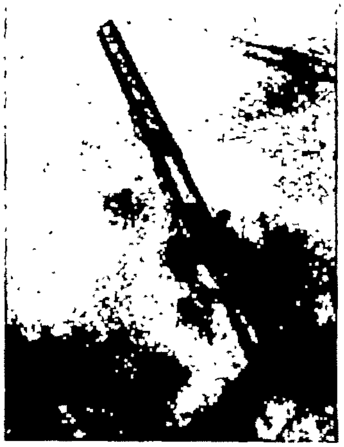

Fig. 1. Autoradiograph showing the accumulation of griseofulvin–chlorine-36 around an infected hair. The bulk of radioactivity is in the keratogenous zone with grains located in the hair shaft of this and the adjacent hair. (× 250)

Autoradiographs obtained in the second experiment demonstrated a denser collection of radioactivity in infected stratum corneum as well as in involved hair follicles. Normal skin showed a pattern of accumulation similar to that seen in uninfected rat skin, and similarly scant. In skin from lesions, however, grains were detected in almost all infected hair follicles, in the suprabulbar and keratogenous zones. Clumps of grains were also seen in infected stratum corneum, extending as far as the stratum granulosum. In a few cases in which parallel periodic acid–Schiff stains were used, the collections coincided with the areas of direct fungal infection. As may be seen (Table 2) direct counts over the lesions showed a higher concentration of radioactivity in these areas than in normal skin (10–20 per cent as contrasted with 2 per cent).

Table 2

Test area of skin	No. of cases	Radioactivity (expressed as per cent of initial value)
Normal	2	1
Infected	8	9–18 (average 12)

The similarity in the distribution of griseofulvin–chlorine-36 and DL-cystine–sulphur-35 in the hair follicles of the rat suggests that the former is taken up during the production of keratin. That it is not intimately involved in the manufacture of keratin is indicated by the limitation of its distribution to the actively growing phase, its interrupted, band-like localization in the hair keratin, and finally, by its failure to appear in quantity in the soft keratin of the stratum corneum. In all these points it differs from radioactive cystine. Studies with radioactive glucose and anions[1] have shown that these are localized in the hair bulb in contrast to those materials directly concerned with keratin. Based on this experience our findings would indicate that the griseofulvin–chlorine-36 molecule remained relatively intact, since our distribution of radioactivity resembled that observed for cations and amino-acids involved in keratin production. This conclusion is supported by the results in the spectrophotometric and radioassays, which also indicate a preferential localization of griseofulvin in keratin sites.

Since the radioactive material did not persist in one site but was carried distally with the keratin, there does not appear to be any intracellular fixation, but rather an incorporation in the interstices of the keratin 'lattice'[2] described by Rudall. This evidence supports the findings of Gentles[3] in which he demonstrated a large water-extractable moiety in skin containing griseofulvin. My failure to demonstrate radioactivity in any quiescent areas of skin suggests the possible inability of griseofulvin to affect fungus situated in necrotic tissue. In work on human skin, griseofulvin was found to concentrate preferentially in infected areas and particularly around sites of fungal accumulation. This might indicate that the associated partial degeneration of infected keratin favours the entrance of griseofulvin into the keratin interstices where its fixation permits a fungistatic action.

I wish to thank the Glaxo Laboratories, Ltd., Greenford, Middx., which supplied the radioactive griseofulvin and carried out the assay of that material.

BIOLOGY

Development of Mouse Eggs beneath the Kidney Capsule

During experiments to produce extra-uterine pregnancies in mice, eggs were transplanted beneath the kidney capsule. Only one egg was transplanted under any one kidney capsule in each experiment. The eggs used were 1-, 2- and 4-cell stages, morulæ and blastocysts.

The transplants were made within a pure line, and within a heterogeneous population. Males and pregnant and non-pregnant females were used as hosts. Results are shown in Table 1.

Table 1

Stage of egg	No. of experiments	No. of positive results	No. of embryos x	No. of *T.G.C.* and *E.M.* y
1 cell	10	8	0	8
2 cell	8	6	0	6
4 cell	8	6	0	6
Morulæ	10	7	0	7
Blastocysts	50	41	16	25

Embryos x = No. of experiments showing embryonic shield derivatives.
T.G.C. and *E.M.* y = No. of experiments showing embryonic membranes and trophoblastic giant cells.

All 36 pre-uterine eggs extracted from the oviduct failed to to produce embryonic-shield derivatives. Fawcett[1], in a similar experiment, transplanted 4–8-cell stage eggs only, and also stated that "differentiation of recognizable tissues or organs of the embryo proper did not occur". In contrast to this result, 16 of the 50 eggs (blastocysts) obtained from the uterus and transferred beneath the kidney capsule gave rise to embryonic shield derivatives. In a number of cases perfectly normal embryos developed (Figs. 1 and 2).

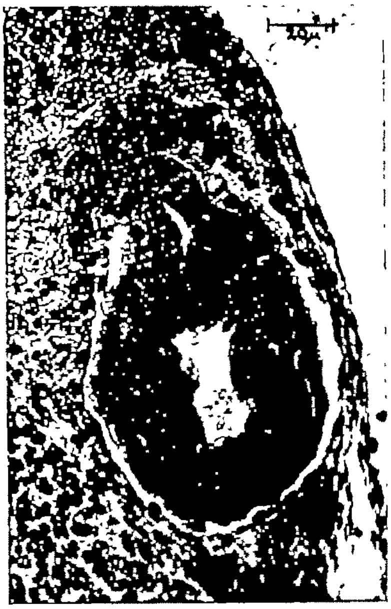

Fig. 1. Sagittal section of embryo embedded in kidney cortex of adult male mouse. Autopsy four days after transplantation of one blastocyst

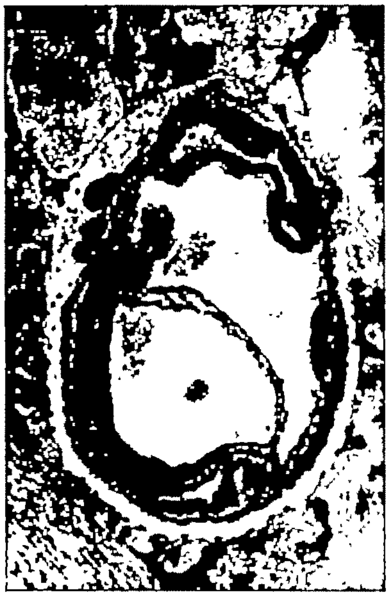

Fig. 2. Section of embryo at head-fold stage with all the embryonic membranes. Autopsy nine days after transplantation of one blastocyst

Nicholas[2], using the rat as experimental animal, transplanted eggs of various stages to the same site and found that only disorganized embryonic tissues developed, and that there was no invasion of the host kidney. In my experiments the embryonic tissues were always surrounded by a matrix of highly invasive trophoblastic giant cells, which caused considerable destruction of the kidney. Lacunæ of extravasated maternal blood lie in the interstices of this matrix of giant cells.

With the progress of invasion of the kidney, the embryonic tissue sinks deeper below the original level of the cortical surface. Compared with intra-uterine gestation, embryos beneath the kidney-capsule are usually retarded in development. Genotype or sex of the host had no effect on the growth of embryonic tissues, except that in transplants to pregnant females the mass of embryonic tissue tended to be larger, but not more differentiated.

I wish to acknowledge with thanks the help given to me by Dr. M. Fischberg. This work was carried out during the tenure of a Research Studentship of the Department of Scientific and Industrial Research.

Cyclical Changes in the Distribution of the Testis Lipids in the Common Frog, *Rana temporaria*

THAT the cytoplasm of the interstitial cells contains fatty substances has been known since as early as 1850 when Leydig reported them in the interstitium of bat, pig, cat and mole[1]. Since then, Leydig cell lipids have been reported in every group from the Agnatha to the Mammalia[2]. Although an enormous amount of work has been carried out on the seminiferous tubules, the majority of workers have used traditional wax-embedding techniques which result in the dissolution of lipids. Thus many aspects of the testis cycle escaped notice until comparatively recent times[3]. It is now known that at the conclusion of spermatogenesis in wild birds, the seminiferous tubules undergo a metamorphosis involving the sudden genesis of large quantities of cholesterol-positive lipids. At about the same time a new generation of Leydig cells arises in the exhausted interstitium[4]. This tubule lipid appears to contain progestogens[5]. Such a complete post-nuptial tubule metamorphosis does not occur in seasonal mammals[6], but it is a regular part of the cycle of certain teleost fishes[7] and has been reported in at least one reptile[8]. It is not known whether Amphibia display comparable events in the seminiferous and endocrine elements of the testis. Few, however, have been studied to this end.

In order to investigate this phenomenon adult male grass frogs (*Rana temporaria*) were collected during every month for one year and the testicular material subjected to a series of histological and histochemical techniques[9].

R. temporaria breeds, in Great Britain, during late February and early March, and specimens killed during this period can be classified into two main groups based on the sudanophil condition of the interstitium and the spermatogenetic condition of the tubules: (1) Those specimens in which sperm shedding has not yet occurred possess tubules filled with bunched and free spermatozoa, scarcely any intra-tubular lipid material and no cholesterol. The interstitium, on the other hand, contains Leydig cells the cytoplasm of which displays numerous lipoidal droplets that give a positive cholesterol reaction when subjected to the Schultz test[10]. Numerous fuchsinophil granules are also present in these cells. (2) Specimens that have discharged their spermatozoa and the tubules of which now possess only spermatogonia and Sertoli cells contain some intra-tubular lipids in the form of a few small Schultz-negative droplets which appear to be in the Sertoli cytoplasm. The interstitial cells are now densely lipoidal and strongly cholesterol-positive (Fig. 1). Fuchsinophil granules have also increased in number. In addition to these two main categories, some autopsied specimens show an intermediate stage in which only some of the testis tubules have discharged their spermatozoa while others still retain theirs. In such gonads the interstitium adjacent to the 'spent' tubules is much more densely filled with cholesterol-rich lipid material than tissue surrounding sperm-containing elements.

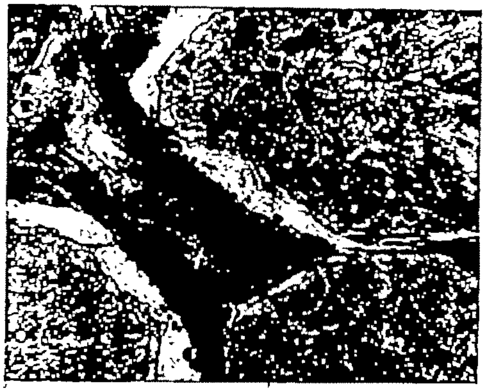

Fig. 1. Frog testis in early March. The 'spent' tubules have not yet become lipoidal but the interstitial Leydig cells are filled with dense cholesterol-positive lipids. (Formol–calcium fixation, sudan-black colouring at 8μ. × c. 250)

As the breeding season progresses, more and more frogs discharge their ripened germinal products and undergo the above-described sequence of events, so that by late March and early April the majority of specimens have passed into their post-nuptial phase and possess testes with Leydig cells in maximum lipid condition and with nuclei measuring $10\mu \times 6\mu$. From then until June prespermatogenesis occurs, during which multiplication of spermatogonia takes place, but these do not develop further than into primary spermatocytes, which thereupon soon degenerate[11,12]. Major changes in the lipid distribution also occur during this period. Leydig cells gradually lose their cytoplasmic cholesterol-rich lipids and fuchsinophil granules, and, accompanying this, there is a shrinkage of the nucleus to an average size of $6\mu \times 4\mu$. In the adjacent seminiferous elements,

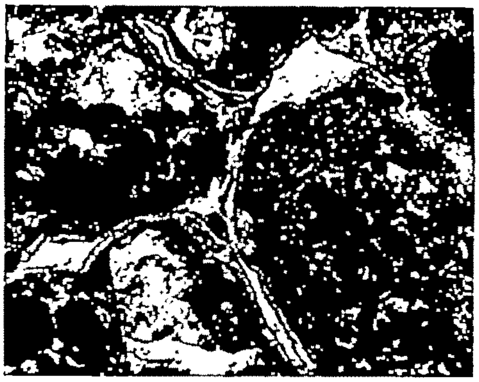

Fig. 2. Frog testis in June. Tubules are now densely lipoidal and cholesterol-positive. Interstitial lipids have disappeared. (Technique and magnification as in Fig. 1)

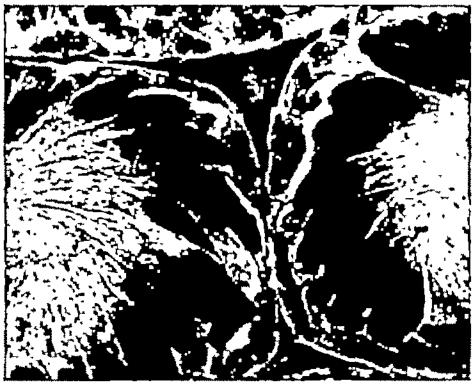

Fig. 3. Frog testis in December. Bunched spermatozoa in tubules. Interstitial Leydig cells have only a few small lipid droplets in their cytoplasm. (Technique and magnification as in Fig. 1)

on the other hand, there is a rapid build-up of intra-tubular lipid. By late June they have increased in size and contain densely lipoidal cytoplasm which now gives a strong cholesterol reaction to histochemical tests. When this Sertoli steatogenesis has reached its maximum level, Leydig cells have lost nearly all lipoidal inclusions (Fig. 2) and become indistinguishable from ordinary connective tissue cells, a condition previously noted by Aron[12]. A few interstitial cell mitoses are seen during this period.

Throughout July and August the tubule lipids disappear and spermatogenesis restarts. This proceeds rapidly and frogs killed in September have gonads in which the seminiferous tubules are once again filled with bunched spermatozoa and contain only small traces of the once profuse intra-tubular lipid material. In the interstitium, Leydig cells are once again starting to develop. This is the so-called static phase[13] during which hibernation occurs. Tubules are at their maximum development and will remain unchanged throughout the winter until sperm discharge in the following breeding season. Although sometimes described as a period of complete testicular inactivity[11], interstitial development does continue. This is revealed by the gradual accumulation of fuchsinophil granules in the Leydig cells, which become more and more numerous during the months of hibernation. The nucleus also increases in size until it once again measures 9μ × 6μ. A few small lipid droplets appear in December (Fig. 3) and by January the majority of Leydig cells contain numerous small lipid droplets in their cytoplasm. Cholesterol is also present from December onwards. In February there is a rapid build-up of interstitial lipid and the animal is once again ready to breed.

These observations reveal that the seminiferous tubules of *R. temporaria* undergo a sequence of cyclical events comparable with those occurring in other sub-mammalian vertebrates. This involves a post-nuptial accumulation of cholesterol-positive lipid within the tubules, and its disappearance when spermatogenesis restarts. This may be of endocrine significance since analysis of similar material in birds has shown it to contain progestogens[5]. The presence of tubule lipid coincides with the period of prespermatogenesis. The interstitial cycle, too, is basically similar to that of birds in that it involves a seasonal accumulation and discharge of cholesterol-positive lipids. But whereas in birds and fishes the Leydig cells gradually discharge the sudanophil contents before mating, the interstitium of the frog contains its maximum lipid content immediately after mating and then becomes slowly exhausted. A similar cycle occurs in seasonal mammals[8]. These events led Champy[11] to suggest that the interstitium of *Rana* was not involved in the development of the secondary sexual characters. However, the sudden increase in lipid and cholesterol in the Leydig cells after sperm shedding does not necessarily imply that the cholesterol is being utilized. On the contrary, it seems not impossible that this phenomenon may indicate that sex hormone secretion, having ceased after copulation, cholesterol is no longer being used in its manufacture, and accumulates. This explanation is supported by the work of Marshall and Wilkinson[14]. These authors found that Orkney voles (*Microtus orcadensis*) seasonally expend their Leydig lipids in apparently the same manner as birds, but that when solitary male voles were placed in complete darkness the cholesterol-positive lipids were no longer used but were stored in the interstitium.

The possible endocrine significance of these events is being investigated by means of chromatography and bio-assay techniques and will be reported elsewhere.

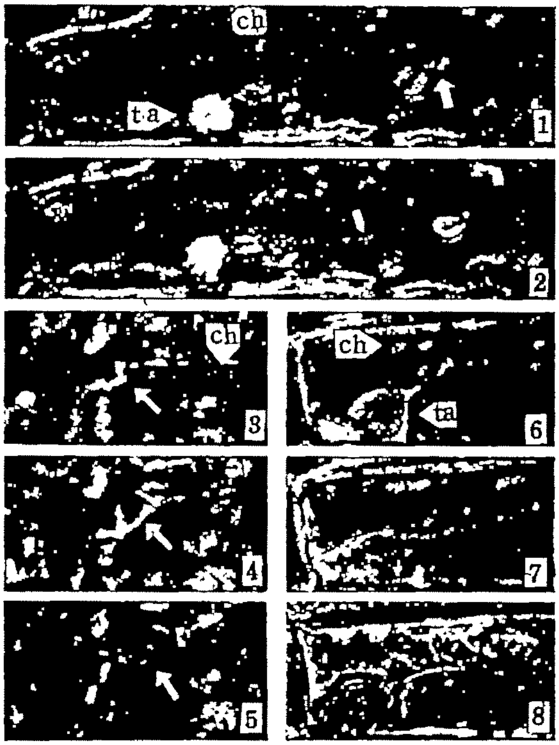
Behaviour of a Thread-like Apparatus in the Petiole of *Mimosa pudica*

Although I have published several communications[1–4] concerning the cytology of the thread-like apparatus in *Mimosa pudica*, these observations were carried out with vital staining and/or with fixation. For a full understanding of the subject, it is necessary to observe the non-treated material in the living state. In this communication, the behaviour of the thread-like apparatus with a phase-contrast microscope is reported.

The sections of the fresh material were prepared in the following manner. Petiole sections were cut 30–50μ in thickness by a hand microtome and by razor, and then sections were immersed in medium solution. All sections were freshly prepared at the beginning of each observation. Observations were made with phase-contrast microscopy in conjunction with dark-medium contrast 100 × objective with a 'Periplan' 10 × ocular. Photomicrographs were



Figs. 1–7. Photomicrographs of the thread-like apparatus of lacunal parenchymatous cells of *Mimosa* petiole, taken with the phase microscope. 1, arrow indicates rosary-like portion; 2, small arrow indicates tiny granule in vicinity of thread; 3–5, vermiculation of a part of thread indicated by arrows; 6, 7, connexion of tannin vacuole and thread-like apparatus. 1–7 are mounted in tap water. 8, caffeine reaction in the same cell of Fig. 7 with bright field microscope (× about 800). *ch*, chloroplast; *ta*, tannin vacuole

taken with a 35-mm. camera attachment (Figs. 1–7). The material in the present work consisted chiefly of those plants which had already received a stimulus. All experiments were carried out at room temperature (25–30° C.) in the summer of 1959.

In the case of the present observations, we must discriminate carefully between the thread-like apparatus and plasma streaming. Furthermore, it is of fundamental importance to distinguish the thread-like apparatus from the other cellular elements. I have attempted the caffeine treatment on the intact cell on the basis of past experience. The reaction of precipitation in the presence of caffeine occurred as one of the specifications of the thread-like apparatus, as was shown previously[1]. The reason for this is simply that caffeine solution was used as a medium after the successful observation of the behaviour of the thread-like apparatus.

The sections were mounted in tap water, without any subsequent treatment, a method deemed most harmless to the protoplasm. In one of the lacunal parenchymatous cells, several minutes after preparation, a movement of the thread-like apparatus began to appear (Figs. 1 and 2). The thread-like apparatus assumed many shapes. A part of the thread is shown as a rosary-like figure or small mass indicated by arrow in Fig. 1, and other parts of the thread are developed to such an extent as to form a long slender structure. Each portion of the thread moves continuously. On careful examination the threads, though not clear in these photographs, are seen to be accompanied by tiny granules. These tiny granules are difficult to photograph in living cells, due to their small size and rapid motion along the thread-like apparatus. But as shown in Fig. 2, successful photographs exhibit a small number of these granules near the thread. The small arrow indicates a tiny granule.

For the purpose of gaining a more complete knowledge of the behaviour of the thread-like apparatus, I made detailed observations on the threads and other cellular elements. The material was soaked in tap-water as mentioned in the foregoing experiment. As shown in the series of photomicrographs (Figs. 3, 4 and 5), the vermiculation of a part of the thread-like apparatus is observable. This vermiculation occurred continuously.

Next, I sought a connexion between the thread-like apparatus and tannin vacuole. The series of photomicrographs show that the thread extends from the tannin vacuole as a horn or a tail (Figs. 6, 7 and 8). In this case, the terminal of the thread was associated with the chloroplasts which were accompanied by tiny granules. Furthermore, caffeine treatment with bright field microscopy was also undertaken (Fig. 8). Accordingly, from the above observation, it seems that the thread-like apparatus is a modified vacuome system of the tannin vacuole.

Recently, Sorokin[6] observed the long filamentous structure in living epidermal cells of the Cichorieae. These filaments branch out, and even anastomose, forming loops and networks under anaerobic conditions. They are regarded as modified plastids. The investigation and the critical comparison of the cellular elements and thread-like apparatus in *Mimosa* must be the subject of future work. The details will be reported in the near future.

Differentiation in *Peronospora tabacina* Adam.

Some results that we have obtained indicate that at least three ecotypes of *Peronospora tabacina* occur in Australia and that the differences between them may prove of importance in breeding for resistance to the pathogen.

Zink[1] reported the occurrence of two races of *P. effusa* (Grev. ex Desm.) Ces. on spinach, and Grabe and Dunleavy[2] described eight races of *P. manshurica* (Naum.) Syd. ex Gaum. on soybeans. Differences between the host-ranges of *P. tabacina* of tobacco in Australia and the United States were reported by Hill[3], who later[4] suggested the possibility of different strains of the pathogen. Within Australia the relative isolation geographically of the major tobacco-growing areas could provide conditions for the development of distinct strains of *P. tabacina*.

On two occasions comparable seedling populations of tobacco breeding lines with some resistance to attack by *P. tabacina* were spray-inoculated with standardized spore suspensions of multispore isolates of *P. tabacina* from North Queensland and Canberra under similar glasshouse conditions. The Canberra isolate was originally introduced from Victoria in

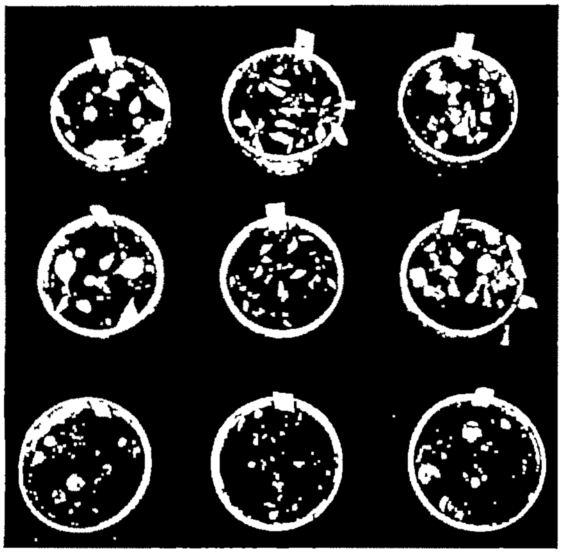

Fig. 1. Disease reaction of three *Nicotiana* spp. to isolates of *P. tabacina* from: front row, Canberra; middle row, North Queensland; back row, Western Australia. The species are: left, *tabacum* L. (var. Virginia Gold); middle, *trigonophylla* Dunal, right, *umbratica*, N. T. Burbidge. Photo 12 days after inoculation

1954. Seedlings showing sporulating lesions within the first 14 days after inoculation were classed as susceptible. The numbers of resistant and susceptible plants in these tests are shown in Table 1. A higher proportion of the plants was susceptible to the Canberra isolates than to the North Queensland isolates, and this was true for all 7 lines which included resistance derived from 3 species.

Groups of four-week-old glasshouse seedlings of 13 spp. of *Nicotiana* which had been obtained as seeds from 33 different localities were inoculated with the two isolates of *P. tabacina* described above and a third isolate from Western Australia. At 7 days after inoculation the amount of sporulation on seedlings grown from the same seed lot was similar for all three collections of the pathogen. In seedlings from 19 seed localities a similar response to infection was maintained as the disease developed with time. In the remaining 14 lots (including *N. tabacum* var. Virginia Gold) the subsequent incidence of disease in the four tests, as recorded after 12 and 20 days and summarized in Table 2, reflected differences due to source of inoculum (Fig. 1).

2	W.A.	C.	or	N.Q.
5	C.	N.Q.	or	W.A.
6	C.	N.Q.		W.A.
1	C.	W.A.		N.Q.

W.A., Western Australia; C., Canberra; N.Q., North Queensland.

Sporulation intensity of the three isolates on *N. tabacum* var. Virginia Gold was determined using the leaf disk technique of Cruickshank and Müller[5]. In two separate tests six disk replications, taken from leaves of plants inoculated with each isolate, were incubated at 20° C. For comparative purposes the Canberra isolate was given a sporulation intensity index value of 100, the corresponding values for the North Queensland and Western Australian isolates being 44·1 and 54·9 respectively. Thus the number of conidia produced by the Canberra isolate was approximately twice that produced under similar conditions by each of the other two isolates.

These results indicate that isolates of *P. tabacina* differ in their pathogenicity range, host reaction and reproductive capacity. The first of these differences, although not so clearly defined at present as those reported for other *Peronospora* spp.[1,2] represents qualitative differences which may be of considerable importance in the development of blue-mould (*P. tabacina*) resistant tobacco varieties. The second and third differences are quantitative only but may be of significance in terms of epidemiology. Environmental conditions favouring spread of the disease occur only periodically, therefore a reduced capacity for reproduction could result in a much slower build-up of the pathogen and a significant reduction in loss due to the disease.

CYTOLOGY

Uptake of Heparin by Cells

IN a previous communication[1] we showed that the epithelial cells and lymphocytes of the thymus gland are capable of being converted into mast cells under conditions of tissue proliferation. With the view of confirming the correctness of this finding, we added partially decomposed heparin in cultures of thymus, spleen and lymph-node tissues and found that the heparinoid substance was taken up considerably by the thymus and by the other two tissues to a lesser extent. The heparinoid matter is then synthesized into complete metachromatic substance in the cells[2]. Tissues obtained from new-born to 1-month-old rats were used in those experiments. We have now attempted to ascertain whether there exists such a difference between the various tissues also in respect of heparin which has not been decomposed and to observe the behaviour of the different tissues in respect to their readiness to take up heparin in the successive phases of ontogenesis.

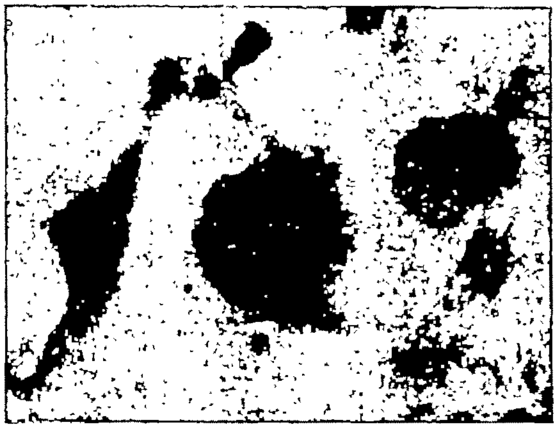

Fig. 1. Cells containing heparin in the culture of thymic tissue taken from 16–17-day-old rat embryo. Toluidine blue. (c. × 400)

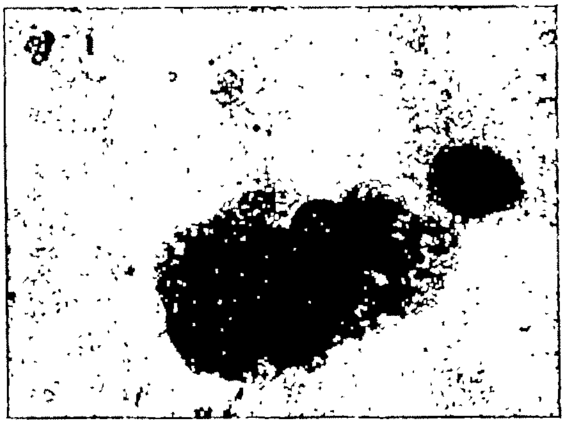

Fig. 2. Cell containing heparin in the thymus of rat weighing 200 gm. Intracellular heparin appears in the shape of coarse lumps. Toluidine blue. (× c. 400)

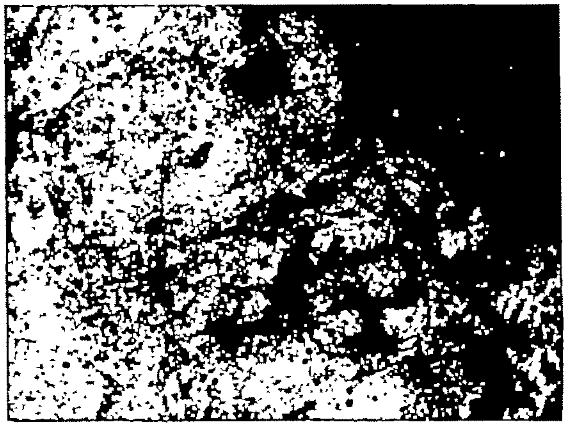

Fig. 3. Formation and disintegration of regular mast cells in the migration zone of the thymus obtained from pregnant rat. Toluidine blue. (× 700)

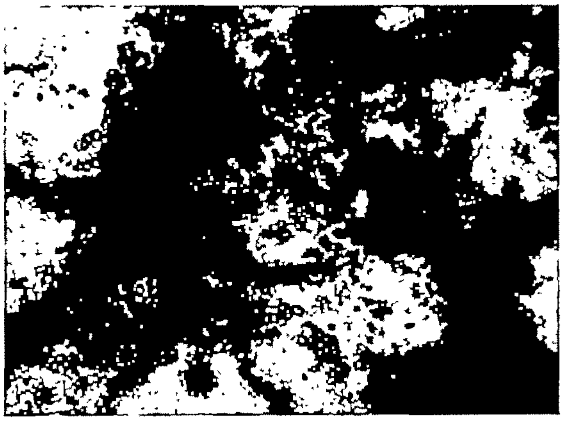

Fig. 4. Enlarged detail of Fig. 3. Toluidine blue. (× 700)

Tissues taken from the spleen, liver, lymph nodes, heart, kidney and thymus of 16-day-old intra-uterine and new-born rats weighing 50 gm., 100 gm., 150 gm. and 200 gm. respectively, and also pregnant and tumorous rats were explanted to Maximow's double cover-slip cultures and grown on a medium consisting of hen plasma coagulated with chick embryo extract. A mixture of horse serum, Tyrode solution and chick embryo extract (3 : 6 : 1) served as bathing fluid. The cultures were first washed 48 hr. after the explantation and again after another 24 hr. The fluid used for this second washing also contained 1 mgm. heparin per 1 ml. of the fluid (heparin pulvis Richter 80 I.U./mgm.). The cultures were fixed in Carnoy's fixing fluid and stained with toluidine blue 48 hr. after the heparin treatment. A total of 800 cultures was divided into two groups.

Experimental results are given in Table 1. The number of cells containing heparin (determined by subjective estimates) is indicated by the number of crosses.

It is evident that all embryonic tissues examined are capable of taking up heparin; kidney and heart of new-born rats are no longer able to do so, and the liver loses this capacity in animals weighing 100 gm. Thymus, spleen and lymph nodes seem to be able to take up heparin throughout the series, and this ability is especially pronounced in the case of the thymus. It can be concluded that all tissues of an embryo, the organs of which contain a great amount of mucopolysaccharides, are capable of taking up heparin, and that—with advancing age—this function is limited to the lymphatic organs, and to the thymus in the first place.

The form in which heparin appears varies according to the age of the animal from which the tissues are taken. Dispersion of heparin granules is very high in the cells of young tissues, and granulation becomes coarser and coarser with advancing age. We regard

Table 1. UPTAKE OF HEPARIN AT DIFFERENT STAGES OF THE RAT'S ONTOGENESIS

Tissue	Embryo	New-born	50 gm.	100 gm.	150 gm.	200 gm.	Pregnant	Tumorous
Spleen	+	+	++	+	+ ?	+ ?	+ ?	–
Liver	+	+	+	–	–	–	–	–
Lymph node	–	+	++	++	+	+	++	+ ?
Myocardium	+	–	–	–	–	–	–	–
Kidney	+	–	–	–	–	–	–	–
Thymus	++	++	+++	+++	+++	++	+++	+ ?

this phenomenon as being more or less in harmony with intracellular colloid-chemical alterations associated with senescence[3-5].

Especial interest is attached to tissues collected from tumorous and pregnant animals. One encounters in them not merely mast-cell-like cells containing heparin but also regular mast cells which disintegrate into granules—a process similar to the disintegration of mast cells contained in the connective tissue. It may be assumed that processes of tissue proliferation involve a factor in the organism which releases cellular disintegration so that, in contradiction to current belief, the break-down of mast cells is not caused by mechanical factors alone.

Cytochemical Evidence of the Origin of Lipid Bodies (so-called Golgi Bodies) from Mitochondria

Since Hirsch's[1] theory of the Golgi presubstance, according to which there exist homogeneous granular mass as a precursor of the 'Golgi' system, there has been very little attempt to investigate the origin of these inclusions in the cell. Nath and Chopra[2] reported the origin of 'Golgi dictyosomes' from mitochondria in the spermatocytes of the slug, *Anadenus altivagus*. However, such a conclusion was arrived at on the basis of morphological study inasmuch as the 'Golgi dictyosomes' disappear at the metaphase and anaphase stages of meiosis I and II, probably merging into the mitochondria; they again appear in the respective telophase stages by the alignment of lipid granules, which seemed to take their origin from the mitochondria. These observations were later confirmed by Nath and Gupta[3] in the living spermatocytes of *Anadenus* and *Euaustenia* under phase-contrast microscopy.

My present cytochemical investigations on the developing oocytes of a large number of species of fish, namely, *Ophiocephalus punctatus*[4], *Barbus ticto*[5], *Mystus tengara*, *Cirrhina reba*, *Labeo dyocheilus*, *Chrysophrys berda*, *Muraenesox talbonides*, *Pseudorhombus elevatus*, *Boleophthalmus dussumierii*[6], clearly demonstrate the origin of lipid granules, corresponding to 'Golgi' granules of earlier workers, from the mitochondria. The earliest oogonia completely lack the 'Golgi' material, and consist of only a juxtanuclear mass of fine mitochondrial granules. However, in the developing oogonia of freshwater fishes, namely, *Ophiocephalus*, *Barbus*, *Mystus*, *Cirrhina* and *Labeo*, the mitochondrial granules align themselves into filaments, while in those of the marine fishes, namely, *Chrysophrys*, *Muraenesox*, *Pseudo-rhombus*, and *Boleophthalmus*, the granular juxta-nuclear mass becomes very dense. In the former case a large number of bigger and denser lipid granules appear as tiny blebs on the surface, and in intimate association with the mitochondrial filaments; but in the latter they develop among the juxta-nuclear mass. However, these inclusions acquire a separate entity in the growing oocytes; they either grow directly into large spheres or attach themselves to tiny vacuoles in the cytoplasm so as to produce rings and crescents.

These 'Golgi' inclusions are very rich in lipid material as revealed by their strong coloration in sudan black *B*. Baker's[7] acid-hæmatin technique with pyridine extraction control reveals the phospholipid nature of the lipid material. However, it changes later into triglycerides as shown by Cain's nile blue technique. The pure lipid nature of these inclusions is demonstrated by the lipid extraction techniques, and is further confirmed by the absence of carbohydrates and proteins, as revealed by periodic acid–Schiff reagent, and Mazia's mercuric bromphenol blue tests, respectively.

Thus it may be concluded from the above results that the mitochondria which always have some phospholipid material in definite configuration with proteins are constantly pinching off phospholipid material in the form of 'Golgi' granules on their surface. The extrusion of lipid material by the mitochondria has also been found by Lever[9] by electron microscopy. Therefore, it seems very probable that the mitochondria also produce 'Golgi' material in the cell, besides their vital oxidative activities.

It may also be stated that the 'Golgi' material always appears in the form of granules in the early stages which may later grow directly into big spheres, or they may come in contact with vacuoles and spread around them to form rings and crescents showing the characteristic duplex structure corresponding to the externum and internum of Hirsch. However, in some cells where 'Golgi' granules lie close together, osmium and silver impregnation tends to make a 'net-work'-like pattern, which is soon resolved in the growing oocytes by their dispersal. These conclusions support Baker's[10] new terminology 'lipochondria' for 'Golgi' inclusions, which would not only signify their granular form and lipid nature but would also indicate their mitochondrial origin.

I wish to thank Prof. Vishwa Nath and Dr. H. S. Roberts for helpful suggestions.

VIROLOGY

Activation of One Plant Virus by Another

Tobacco necrosis is a disease that can be caused by several serologically unrelated viruses[1], all of which are soil-borne and cause necrotic local lesions in leaves of tobacco (*Nicotiana tabacum* L.) and French bean (*Phaseolus vulgaris* L.) plants. The virus Bawden and Pirie[2,3] called the 'Rothamsted culture' differed in several respects from other members of the group; the ratio of infectivity to specific antigen content varied greatly in different preparations, it lost infectivity *in vitro* more rapidly than the others, and infective preparations always contained particles of two different sizes, about 17 mμ and about 30 mμ in diameter. Crystalline preparations (identified as nucleoproteins), consisting almost entirely of the smaller particles, had little or no infectivity, whereas other partly purified preparations that contained many more of the larger particles were infective. From this, Bawden and Pirie concluded that probably only the larger particles were infective and that the smaller ones, which were usually the major constituent of their preparations, were an additional product of the multiplication of the larger ones[4].

We have now found that the large and small particles in the Rothamsted tobacco necrosis are serologically unrelated, and that whereas the large particles can apparently multiply by themselves, the small ones multiply only in the presence of the large. Particles having different sedimentation-rates were separated from partly purified virus preparations, made as described by Bawden and Pirie[5], by centrifuging in sucrose density gradients[6]. After sedimenting for 2 hr. at 17,000 r.p.m. (about 25,000*g* at the top of the gradient column), two and sometimes three light-scattering zones were formed. The top zone contained particles 17 mμ in diameter, the second one particles 30 mμ in diameter, and the third zone, when present, contained aggregates each apparently consisting of a group of 12 of the 17 mμ particles. The approximate sedimentation constants, estimated from the depths of the zones as described elsewhere[7], were 45*S*, 116*S*, and 216*S*, respectively, assuming the value for tobacco mosaic virus to be 187*S*. These three components presumably correspond to those reported as having sedimentation constants of 51, 116 and 240*S* (ref. 2).

When material from each of these zones was inoculated separately to French bean or tobacco plants, only that from the middle zone produced lesions, and these were more uniform in size than those produced from inocula made by extracting sap from diseased plants. In one experiment, when these leaves inoculated from the middle zone were later macerated and the virus from them extracted and purified, the ratio of 30 mμ to 17 mμ particles was 21 : 1. Similar leaves, inoculated with a mixture of equal volumes of top zone and middle zone material, gave a ratio of 1 : 1. Leaves inoculated with either top or bottom zone material alone failed to develop lesions, and extracts from such leaves showed no virus-like particles when examined with the electron microscope. When tested in double-diffusion precipitin tests in agar gel against an antiserum containing antibodies to both large and small particles, the extracts from plants inoculated with middle zone material gave one line, those from plants inoculated with mixtures of top and middle zone gave two lines, and those from plants inoculated separately with top or bottom zone only gave no lines.

Table 1 shows the effects of using as inocula particles from the middle and top zones. Mixing the two decreases the size of the lesions below that produced by the middle zone alone.

Table 1. INFECTIVITY OF SMALL AND LARGE PARTICLES SEPARATELY AND WHEN MIXED IN DIFFERENT PROPORTIONS

Inocula	Numbers of lesions on seven half-leaves of French beans	
	Large lesions	Small lesions
Large particles, 4 mgm./l.	322	0
Large particles, 4 mgm./ml. + small, 5 mgm./l.	12	314
Large particles, 4 mgm./ml. + small, 20 mgm./l.	4	295
Large particles, 4 mgm./ml. + small, 80 mgm./l.	1	184
Small particles, 80 mgm./l.	0	0

A small proportion of small particles did not alter the total number of lesions, but only a few were now large. Further successive increases in the proportion of small particles in the inoculum did decrease the total number of lesions, and almost all were small.

These results indicate that the small particles interfere with, and when abundant may even suppress, the multiplication of the large particles, and that they multiply detectably only when inoculated together with the large ones. It seems likely that a pure preparation of large particles would infect and multiply without producing any of the small particles, but it is impossible to establish this because the middle zone cannot be removed from the centrifuge tube without some contamination from top or bottom zones. However, our results clearly suggest that the number of small particles produced in the inoculated leaves depends upon the proportion of small particles in the inoculum.

The production of non-infective particles along with infective ones has been described before with other viruses, but in all such examples known to us the non-infective particles are serologically related to the infective ones so that they can be regarded as products of the synthesis of one virus. The association of two sizes of particles in the Rothamsted tobacco necrosis culture appears to be unique, for the two kinds of particles are serologically unrelated and thus seem to be separate viruses, one of which is apparently completely dependent upon the other for its multiplication.

Infective Ribonucleic Acid from the Viruses of Talfan and Teschen Diseases

INFECTIVE ribonucleic acids have been obtained from several animal viruses by the cold phenol method described by Gierer and Schramm[1]. In general, however, most of the experiments have been done with crude suspensions, and it has not always been clear whether the infective ribonucleic acid was derived from the virus itself or from a viral precursor or other related material. The work of Huppert and Sanders[2] with mouse encephalomyocarditis virus has shown clearly that the infective ribonucleic acid which can be obtained from mouse carcinoma cells infected with this virus has its origin in a viral precursor and not in the virus itself. In fact, infective ribonucleic acid cannot be extracted from this virus by the cold phenol method. On the other hand, it is likely that the infective material which can be obtained from suspensions of tissues infected with the viruses of poliomyelitis[3], mouse encephalomyelitis[4], Mengo encephalitis[5], Murray Valley encephalitis[6] and foot-and-mouth disease[7,8] by this method is being derived from the viruses themselves. This difference in behaviour emphasizes the differences in the chemical structures of the viruses. Furthermore, the work of Wecker[9] has shown that purified Western equine encephalomyelitis virus, which does not yield any infective ribonucleic acid on treatment with cold phenol, can be made to do so if the extraction is carried out at 40–50° C.

Similar experiments have now been done with the viruses of Talfan and Teschen diseases. Talfan disease is a recently described[10] polioencephalomyelitis affecting young pigs in Britain and shows close similarities to Teschen disease, an infection of pigs well known in Europe. The cross-neutralization tests described by Chapronière, Done and Andrewes[11] suggested that the two diseases are caused by identical or similar viruses. The preliminary results described here show that the infective material which can be obtained from suspensions of each virus by treatment with cold phenol is a ribonucleic acid which is being extracted either from the virus itself or from a material which sediments along with the virus in the ultracentrifuge.

Tissue culture fluids were harvested from pig kidney cell monolayers 24–30 hr. after infection. After this period of incubation, all the cells were off the glass and the virus titre was at a maximum. The virus suspensions were concentrated by dialysis against polyethylene glycol[12] at 2° C. These concentrates were then centrifuged at 30,000 r.p.m. for 1 hr. in the *L* 30·2 head of the 'Spinco' ultracentrifuge. The top 7 ml. (supernatant fraction) of each tube was then removed and the pellet suspended in the lower 2 ml. diluted with a further 7 ml. of tissue culture medium (deposit fraction). The virus content of the initial concentrate and of each fraction was determined by observing the number of plaques formed on pig kidney cell monolayers. Tenfold dilutions were used, and the monolayers stained with neutral red after 96 hr. incubation. Phenol extracts were prepared from each fraction and 0·4 ml. aliquots inoculated on to pig kidney cell monolayers in 4-oz. bottles. Four bottles per tenfold dilution were used and the monolayers were examined daily for cytopathic effects. The results (Table 1) show that infective ribonucleic acid could not be detected in the phenol extracts of the supernatant fractions but only in the deposit fractions. This is similar to the results we have obtained previously with foot-and-mouth disease virus[7], but is in direct contrast to those obtained with mouse encephalomyocarditis virus[4]. In the latter case, infective ribonucleic acid could be obtained from the supernatant fraction only, although this contained less than 0·1 per cent of the initial virus.

The cytopathic effects produced by the phenol extracts could be prevented by incubating them with 10 μgm. ribonuclease/ml. for 15 min. at 20° C. prior to inoculation on to the monolayers. As the titre of the parent viruses was not affected by adding 10 times this amount of the enzyme to each virus dilution, it seems probable that the infective agent in the phenol extracts is a ribonucleic acid.

Table 1. YIELD OF INFECTIVE RIBONUCLEIC ACID FROM ULTRACENTRIFUGE FRACTIONS OF TESCHEN AND TALFAN VIRUSES

Virus	Fraction	Virus titre (p.f.u./ml.)	Ribonucleic acid titre (log *ID*50/ml.*)
Talfan	Initial	$3 \cdot 6 \times 10^8$	2·2
	Supernatant	$1 \cdot 0 \times 10^5$	None detected
	Deposit	$2 \cdot 5 \times 10^8$	2·2
Teschen	Initial	$2 \cdot 4 \times 10^8$	2·0
	Supernatant	$1 \cdot 3 \times 10^4$	None detected
	Deposit	$1 \cdot 5 \times 10^8$	2·2

* 0·4 ml. inocula used.

The fluids harvested from those monolayers which showed cytopathic effects following infection with the ribonucleic acid had properties similar to those of the intact viruses. They were neutralized by antisera prepared by inoculation of the viruses into rabbits. Thus 100 *ID*50 of the parent virus or the ribonucleic acid harvest was neutralized by an equal volume of 1/1,000 homologous rabbit antiserum, as measured in pig kidney cell suspensions by the metabolic inhibition test (Martin, W. B., and Chapman, W. G., unpublished work). The possibility that the neutralization was an anti-tissue effect of the sera was rejected, as the same sera had no effect on the titration end-point of foot-and-mouth disease virus (strain 997, Waldmann type *O*) in the same cell system.

We wish to thank Mrs. J. O. Farley for the rabbit antisera and Dr. W. B. Martin and Mr. W. G. Chapman for furnishing us with details of the metabolic inhibition test prior to publication.

Polyoma Virus Mutant with a Reduction in Tumour Formation

INFECTION with polyoma virus *in vivo* can result in a cytopathic effect, hyperplasia, and the formation of benign or of malignant tumours[1]. The use of single plaque isolations has indicated that these different types of response can be produced by the same virus[2]. During the course of investigations on the induction of different responses to virus infection *in vitro*, a plaque-type mutant of polyoma, with a smaller-sized plaque than the wild type, was found in the virus produced by a line of mouse cells with a stable cell-virus association[3]. This line of cells was established by the culture of survivors after cytopathic effect in primary mouse embryo monolayers that had been infected with wild type polyoma. The cell line has now been releasing virus in culture for more than

1 year, and the plaques made by the virus are still of the mutant type. The mutant has been designated as *sp* (= small plaque). Cross-neutralization of plaques has so far shown no antigenic difference between *sp* and the wild type.

sp virus harvested 8 months after the establishment of the cell line was tested for tumour induction *in vivo*. In contrast to a 100 per cent incidence of animals with tumours after inoculation of wild type polyoma into hamsters, even with an input of 1·0–3·0 × 10^5 plaque-forming units of *sp* per animal, only subcutaneous sarcomas were found in 3 out of 31 hamsters (Table 1). One litter of *AKR* mice was inoculated when 2 days old with *sp*, and during an observation period of 6 months, parotid tumours only were observed in 1 out of 5 animals, in contrast to a 100 per cent tumour induction after inoculation of wild type virus.

Table 1. TUMOUR INDUCTION IN HAMSTERS AFTER INOCULATION WITH WILD TYPE POLYOMA VIRUS AND THE MUTANT *sp*

Virus	No. of litters	Age at inoculation (days)	Input virus per animal (plaque-forming units)	Observation period (months)	No. with tumour / No. of animals
Wild type	6	3 to 6	1 0 × 10^5	2 5	30/30
sp	3	2 to 4	1 0 to 3 0 × 10^5	2 5	1/16
	3	3 to 6	1·4 to 2 0 × 10^5	3 to 4	2/15

Animals inoculated subcutaneously with 0 1 ml. of virus suspension.

These results show that it is possible to obtain, with a tumour virus, a mutant that is 'attenuated' regarding its tumour-producing capacity, while retaining its cytopathic effect. The existence of complete attenuation for tumour-producing capacity, and of the reverse type of mutant, that is, tumour production without cytopathic effect, is now being looked for. It is of interest that in common with the *d*[4] and *MS*[5] mutations of polyomyelitis that can be associated with reduced neuropathogenicity, the reduced tumour induction by this polyoma mutant is also associated with a plaque type mutation.

Virus and Antibodies in the Lymph and Blood of Sheep infected experimentally with the Virus of Tick-borne Encephalitis

IT is known that foreign substances which penetrate the organism are resorbed by the lymphatic system. This also applies to bacteria and viruses

In previous experiments[1] it was found that when tick-borne encephalitis virus was administered subcutaneously to mice, it was resorbed via the regional lymph vessels into the blood stream, from which it afterwards penetrated further lymph vessels and other organs. This was demonstrated by detecting the virus in the lymph nodes and blood.

Since I was interested in the question of the part played by the lymphatic and blood vascular systems in direct resorption of the virus from infected tissue; in their time relationships and in the antibody response in the lymphatic system, it was necessary to increase the accuracy of the preceding experiments by examining more adequate systems, namely, lymph and blood.

The experiments were carried out in sheep with an artificial lymph-blood circulation[2]. Lymph was collected from the cannulated thoracic duct and blood was obtained from a contralateral vein (one of the branches of the right jugular vein). The virus was detected in mice by intracerebral infection. Neutralizing antibodies were determined by an intraperitoneal test in mice.

The experiments clearly demonstrated that the lymphatic system is the main route by which the virus penetrates the blood stream from the subcutaneous tissue. No direct resorption of the virus from the subcutaneous tissue into the blood stream was found. If this occurs at all, it is evidently on such a small scale that it cannot be detected by the method used. The rate of resorption by the lymphatic system depends on the amount of virus. When administered subcutaneously into the metatarsus of the hind limb in amounts of 0 043 ml. 20 per cent suspension/1 kgm. body-weight (about three to four thousand million intracerebral mouse *LD*50), the virus was detected 60 min. later in lymph collected from the thoracic duct. No penetration of the virus into the blood stream from any part of the lymphatic system other than the thoracic duct was observed. Following re-infection seven and twelve days after primary inoculation, the virus was not detected in the lymph or the blood, even at very early intervals after reinfection[3].

Neutralizing antibodies were detected in the lymph sooner and in higher titres than in the blood plasma. Antibodies were also determined in the lymph of a sheep in which the thoracic duct was exteriorized and its connexion with the blood stream was interrupted, so that the virus, which was administered into a peripheral lymph vessel, passed through the regional lymph vessels only. This means that antibodies were determined in the lymph after antigenic stimulation to which, in effect, only the regional lymph vessels were exposed. The first antibodies were always found when the virus rapidly decreased in the lymph and in the blood. The higher antibody titre in the lymph was maintained up to the seventh day after infection. From then onwards it was higher in the blood plasma. Re-infection on the seventh and twelfth day after primary inoculation resulted in a further antibody increase in the lymph and the blood plasma, which was greater in the latter[4].

These experiments show that the lymphatic system plays an important part in resorption and transport of the tick-borne encephalitis virus and in the formation of antibodies against it.

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

BRANCH PRINCIPAL (with a good degree and suitable experience in universities or technical colleges) OF THE ENUGU BRANCH of the Nigerian College of Arts, Science and Technology—The Council for Overseas Colleges, 12 Lincoln's Inn Fields, London, W.C.2 (August 26).

LECTURERS (with an honours degree, or equivalent, in engineering or applied science, and industrial, research or teaching experience) IN MECHANICAL ENGINEERING—The Registrar, Royal Technical College, Salford, Lancs (August 31).

RESEARCH FELLOW (microbiologist with postgraduate research experience, and preferably experience in microbial genetics) IN MICROBIOLOGY, to join a research team of chemists and microbiologists concerned with fundamental studies on biosynthesis—The Registrar, University College, Singleton Park, Swansea (August 31).

PHYSIOLOGISTS (ASSISTANT LECTURERS, LECTURERS, or SENIOR LECTURERS) (with a degree in physiology, of honours standard, and for one of the appointments preference will be given to a candidate with postgraduate training and research experience in the field of human physiology) IN THE NEW DEPARTMENT OF ERGONOMICS AND CYBERNETICS, for research and postgraduate teaching in ergonomics—The Academic Registrar, Loughborough College of Technology, Loughborough, Leicestershire, quoting Ref. 17/AF (September 1).

RESEARCH ASSISTANT (preferably with research experience) IN THE DEPARTMENT OF BOTANY, for work in translocation in plants—The Secretary, The University, Aberdeen (September 3).

SENIOR LECTURER or LECTURER (with special qualifications either in plant pathology or virology) IN BOTANY—Joint Clerk to the University Court, Queen's College (University of St. Andrews), Dundee (September 8).

ASSISTANT DIRECTOR OF RESEARCH IN DYNAMICAL OCEANOGRAPHY in the Department of Applied Mathematics and Theoretical Physics—Dr. F. G. Friedlander, Secretary of the Appointments Committee of the Faculty of Mathematics, the Arts School, the University, Bene't Street, Cambridge (September 9).

ASSISTANT LECTURER (graduate, with special interests in either igneous petrology or sedimentary petrology and palaeozoic stratigraphy) IN GEOLOGY—The Registrar, The University, Leicester (September 10).

LECTURER (with a good honours degree in electrical engineering or physics, preferably of a British university, together with some industrial experience, and preferably some teaching experience and a special knowledge of microwave engineering) IN ELECTRICAL ENGINEERING—The Secretary, University College, Gower Street, London, W.C.1 (September 10).

ASSISTANT EXPERIMENTAL OFFICER (with a pass degree or five subjects at G.C.E. "O" level and at least two at "A" level) IN THE DEPARTMENT OF POTATO GENETICS, to assist in routine tests and pathological investigations—The Secretary, John Innes Institute, Bayfordbury, Hertford, Herts (September 12).

SENIOR LECTURER IN HORTICULTURE at the University of Sydney, Australia, to undertake teaching and research in fruit and vegetable production—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, September 13).

EXPERIMENTAL OFFICER (MICROBIOLOGIST) (with experience in the isolation and maintenance of pure bacterial cultures, and preferably experience in the biochemical techniques) at the National Chemical Laboratory, D.S.I.R., Teddington, Middlesex, to join a team studying the influence of micro-organisms on corrosion of metals, particularly in soil—The Ministry of Labour, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting G.275/0A (September 19).

BOTANIST or BIOCHEMIST (with an interest in field work), to grow and test plants for suitability as sources of protein—The Secretary, Rothamsted Experimental Station, Harpenden, Herts (September 20).

LECTURER IN ANATOMY at the University of Western Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, September 30).

SENIOR LECTURER IN PHYSICS, and LECTURERS (2) IN PHYSICS at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, September 30).

PHYSICIST or CHEMIST, Scientific Officer grade (male, with a first- or second-class honours degree, and preferably experience of polymers or biological systems or ionizing radiation), at the Royal Military College of Science, Shrivenham, for a two- or three-year programme of fundamental research (of an academic character and intended for publication) on effects of high energy radiation of polymers in solutions, and the effect of additives as a means of radiation protection or enhancement. This work would be correlated with corresponding effects in biological systems—Technical and Scientific Register (K), Ministry of Labour, 26 King Street, London, S.W.1, quoting A.326/0A (October 6).

AGRICULTURAL OFFICER (EDUCATION) (male, with a degree in agriculture or natural science, at least two years suitable postgraduate experience or training, and preferably some teaching experience) in Nyasaland, to teach agricultural subjects to African students at the Colby School of Agriculture near Lilongwe—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD.63/4/023/T.

ASSISTANT LECTURER (Grade B) IN MATHEMATICS—The Clerk to the Governors, Chelsea College of Science and Technology, Manresa Road, London, S.W.3.

ASSISTANT (with a degree in botany or agriculture, and preferably experience of plant pathology) TO THE MYCOLOGIST—The Secretary, National Institute of Agricultural Botany, Huntingdon Road, Cambridge.

BIOLOGIST (with a good degree in physiology or zoology and considerable research experience preferably with spermatozoa), to join a small research team investigating cervical mucus, with particular reference to problems of fertility—The Secretary, National Institute for Research in Dairying, Shinfield, Reading, quoting Ref. 60/13.

CHEMISTS, MATHEMATICIANS (including STATISTICIANS), METALLURGISTS, MECHANICAL AND ELECTRICAL ENGINEERS, and PHYSICISTS (including BIOPHYSICISTS) (men and women, with a first- or second-class honours degree or equivalent) at Research and Development Establishments of the War Office at various locations, including Sevenoaks, Kent; Byfleet, Chertsey and Tolworth, Surrey; Shoeburyness, Essex; Christchurch and Farnborough, Hants; Salisbury, Wilts; and in Cornwall—Technical and Scientific Register (K), Ministry of Labour, 26 King Street, London, S.W.1, quoting A.300/0A.

DEMONSTRATOR IN AGRICULTURAL ZOOLOGY at the School of Agriculture, Sutton Bonington—The Registrar, The University, Nottingham.

ELECTRONICS TECHNICIAN (male or female), for research work—Dr. E. Bulbring, Department of Pharmacology, The University, South Parks Road, Oxford.

EXPERIMENTAL OFFICER or ASSISTANT EXPERIMENTAL OFFICER (preferably with a degree in dairying, or the N.D.D., together with good experience of laboratory work) IN THE BACTERIOLOGY DEPARTMENT, to work on hygienic aspects of milk production and processing—The Secretary, National Institute for Research in Dairying, Shinfield, Reading, quoting Ref. 60/8.

EXPERIMENTALIST (with G.C.E. at "A" level, H.N.C. in applied physics or equivalent qualifications and preferably an interest in electronics) IN THE METALLURGY DIVISION, A.E.R.E., to assist with experimental measurements for the study of solids by diffracting beams of neutrons from nuclear reactors—The Personnel Manager (1747/34), United Kingdom Atomic Energy Authority, Atomic Energy Research Establishment, Harwell, Didcot, Berks.

GEOLOGISTS (not over 35, with a first- or good second-class honours degree in geology) with the Government of Northern Nigeria, for regional geological mapping and the examination of mineral deposits—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD.105/3/01.

HONOURS GRADUATE (preferably in physics), for work on electrical and mechanical properties of ceramics at ordinary and elevated temperatures—The Director of Research, British Ceramic Research Association, Queens Road, Penkhull, Stoke-on-Trent.

LABORATORY TECHNICIAN (with some training in bacteriological technique and preferably with Inter I.M.L.T.)—The Secretary, Royal Veterinary College, Royal College Street, London, N.W.1.

MALE SPECIALIST VIROLOGIST (with qualifications registrable in the United Kingdom, and a minimum of seven years postgraduate experience, at least five of which must have been spent in the practice of virology) in Hong Kong, to take charge of the Vaccine Institute and the manufacture of human and animal vaccines—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD117/51/062.

PHYSICAL CHEMIST (with at least five years research experience) IN THE RESEARCH LABORATORIES, initially to lead a team studying the bulk properties of high polymers—The Director, Arthur D. Little Research Institute, Inveresk, Midlothian, Scotland.

PHYSICAL CHEMIST (with doctorate, preferably with experience in low temperature calorimetry), for academic research in the thermodynamic properties of compounds of biochemical interest—Institute of Scientific Research, New Mexico Highlands University, Las Vegas, New Mexico, U.S.A.

PLANT PHYSIOLOGIST (with a good honours degree in botany or chemistry with specialization in plant physiology and not less than two years suitable postgraduate experience or training) in Tanganyika, for research work on coffee, with particular reference to over bearing and plant nutrition, and to collaborate with other specialists—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD.63/8/026/T.

POST-DOCTORAL FELLOWS IN THE DEPARTMENT OF CHEMISTRY, for research work in the fields of electron spin resonance spectroscopy of free radicals at liquid helium temperature, and mass spectroscopy including photo-ionization studies—Prof. C. A. McDowell, Department of Chemistry, University of British Columbia, Vancouver 8, B.C., Canada.

POST-DOCTORAL RESEARCH FELLOW IN THE DEPARTMENT OF ORGANIC CHEMISTRY, for work on biosynthesis in fungi and bacteria—The Registrar, The University, Liverpool, quoting Ref. CV/N.

RESEARCH ASSISTANT (PHYSICIST) (with a knowledge of electronics and a degree in physics), for work with the X-ray scanning micro-analyser (electron probe) in the field of ore microscopy—Dr. A. P. Millman, Mining Geology Department, Royal School of Mines, Prince Consort Road, London, S.W.7.

SCIENTIFIC ASSISTANT (ABSTRACTOR) (with a degree in agriculture or natural science and a knowledge of languages)—The Director Commonwealth Bureau of Pastures and Field Crops, Hurley, Berkshire.

SENIOR LECTURER IN SERVOMECHANISMS AND CONTROL ENGINEERING, a SENIOR LECTURER IN STRUCTURAL ENGINEERING, a SENIOR LECTURER IN ENGINEERING DRAWING, a LECTURER IN THE STRENGTH OF MATERIALS AND ELASTICITY, a LECTURER and an ASSISTANT LECTURER IN APPLIED MECHANICS, a LECTURER IN ENGINEERING DRAWING, a LECTURER IN THERMODYNAMICS, a LECTURER IN PRODUCTION ENGINEERING, and a LECTURER IN CHEMICAL ENGINEERING, IN THE DEPARTMENT OF MECHANICAL, CIVIL AND CHEMICAL ENGINEERING—The Secretary, Royal College of Science and Technology, George Street, Glasgow, C.1.

SENIOR LECTURER (with good teaching experience, together with research or industrial experience) IN INORGANIC or IN PHYSICAL CHEMISTRY—The Principal, Huddersfield College of Technology, Huddersfield.

SENIOR SCIENTIFIC GLASSBLOWER (well qualified, with considerable experience in high vacuum techniques, metal/glass seals, quartz work, etc.) IN THE DEPARTMENT OF CHEMISTRY—The Secretary, Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada.

SENIOR TECHNICIAN II, to take charge of the Biochemistry Department in the Group Laboratory, Connaught Hospital, Walthamstow—The Secretary, Forest Group H.M.C., Langthorne Road, London, E.11.

SPECIALIST OFFICER (PLANT PATHOLOGIST) (with a university degree in natural science (botany) with first- or second-class honours, and two years postgraduate experience in plant pathology) IN THE DEPARTMENT OF AGRICULTURAL RESEARCH, Ibadan, Nigeria, to undertake research into virus diseases of food crops—The Appointments Secretary, Federal Public Service Commission, Nigeria House, 9 Northumberland Avenue, London, W.C.2, quoting B.7/2.

TECHNICIAN (with some knowledge of, and interest in, insects or spiders)—Prof. G. C. Varley, Hope Department, University Museum, Oxford.

VISITING ASSISTANT PROFESSOR-RESEARCH ASSOCIATE, to give some lectures in general chemistry and in an advanced course in inorganic chemistry, help with the supervision of laboratory work, and engage in research in inorganic chemical synthesis or reactions—Louis J. Bircher, Box 1550, Vanderbilt University, Nashville 5, Tennessee, U.S.A.

UNIVERSITY EDUCATION IN BRITAIN

In the stimulating discussion of the diffusion of knowledge, to which he devoted his Foundation Oration at Goldsmiths' College, University of London, last March, Dr. Michael Grant pleaded for recognition of the task of exposition as worthy in itself and demanding high qualities of skill in interpretation and even scholarship; he also urged that a university should study deliberately how to produce the habit of mind which would make its students want, both before and after graduation, to take an open-minded interest in at least something worth while outside their own careers. The schools can do little to help, but the universities could give their students the habit of mind which would enable them to enjoy and benefit from reading about subjects other than their own, written in comprehensive terms.

Much the same point of view was taken by Prof. J. A. B. Gray in an inaugural lecture at University College, London, on February 23, on the place of physiology in university education*. He enumerated four main aims of formal courses: the provision of professional training; teaching people to understand the language used by experts and to be able to assess the value of their opinions; training the undergraduate to interpret evidence and to make sound judgments; and to develop a sense of values. He placed them in that order of increasing difficulty of achievement and increasing importance. Men with a sound professional training can increase material standards of living, but Prof. Gray believes that if our society is to make progress, the universities must provide men and women who are not overawed by the opinions of experts, who can assess the real worth of propaganda, pressure groups and advertising, and who have a sense of values, and his lecture discussed the possibility of physiology providing a basis for such an education in the universities as they are to-day.

Prof. Gray did not, of course, attempt to deal comprehensively with modern physiology, but limited himself to the discussion of certain problems connected with the physiology of receptors and sensory mechanisms. Pointing out that the most challenging of all problems connected with sensory mechanisms is to be found in the problem of human knowledge itself, and that our mental image of the world is determined by the ability of our receptors to detect the very narrow band of electromagnetic waves that we call light, he suggested that the development of receptors having very high sensitivities to events in the environment, and so small that animals can employ large numbers of them, should be regarded as one of the most significant factors in the adaptation of life to its environment and in the evolution of man himself. The width of the contacts which a physiologist working in this field should have with other branches of knowledge illustrates the contribution which physiology could make to his four aims of university education.

One of the problems with which the modern world is faced is the great increase in the use of specialized knowledge, and at the same time a decrease in the breadth of what is known by any one person. Many people, whether they are in a profession, in government service, in industry, or in academic life, are constantly needing advice from experts, and frequently have to judge between the opposing opinions of experts in entirely different fields. The point of decision may be in the general administrative field but it is frequently on what is a professional or scientific matter, and Prof. Gray observes that it is a great help to know what the other person is talking about and what sort of questions ought to be asked. Physiology, he thinks, has much to offer in this way because of its central position among university subjects, and he also believes that it could be made a gateway to science for those reading for an arts degree and who wish to take up a career in administration, because physiology sets out to answer certain of the human problems that they are likely to have met in their studies of human thought. Apart from this, physiology, as already noted, will bring the student into contact with ideas derived from most branches of science.

Prof. Gray readily admits that to have any hope of success such a course of physiology would have to differ considerably from those run to-day. He also claims that physiology can train a man to interpret evidence and make sound judgments from it and that accordingly it can provide a sound education for those who are looking for a non-specialist career in administration or industry. Finally, he suggests that physiology is able to bring the student face to face with questions of value and responsibility. Its subject-matter is the mechanisms of life, and this in itself tends to stimulate the intelligent student into asking himself or discussing with others questions about the meaning of life and about the nature of mind and consciousness.

As regards the nature of the courses to serve these several purposes Prof. Gray holds that the need of each of the different classes of students should be considered on its own merits and that courses should be constantly developing and changing to meet the challenge of new demands. Indeed, in his view, physiology itself will only flourish if it is in a position to draw help and inspiration both from other branches of knowledge and from the applications which it serves. It is an advantage to have specialist departments in certain specialist institutions, but as with many other subjects, the roots of physiology will lie in departments which are not only located in multi-faculty institutions but also are actively working in more than one faculty.

---

* The Place of Physiology in University Education. By Prof. J. A. B. Gray. (Inaugural-lecture delivered at University College, London, 23 February, 1960.) Pp. 16. (London: H. K. Lewis and Co., Ltd., 1960.) 2s. 6d. net.

There is thus some critical thinking already going on in the universities of Britain about the nature and re-shaping of university education; the plea which the Duke of Edinburgh advanced, in opening the Conference of the United Nations Educational, Scientific and Cultural Organization in London on humanism and technology, for a proper balance between science and humanism should fall on fertile ground. No one, he said, trained for a scientific post could hope to make his full contribution unless he has a broadly cultivated mind, and it is very doubtful, he suggested, whether a traditional scholar could really claim to make any contribution to philosophy in the technological age if he is utterly ignorant of scientific facts. Sir Julian Huxley added that, in the long run, it is perhaps of most importance to educate people as human beings and there is need for a background of approach to our thought which sees man as trustee for the whole of this planet and all those on it.

Clearly we are here touching the fundamental question of the real purpose of a university education, and in the debate in the House of Lords on May 11 on university and other higher education in Britain this was urged by several speakers as one of the most important questions requiring study, if not by a Royal Commission, then by something in the nature of a Crowther Committee or the University Grants Committee itself. Indeed, Lord Beveridge, in urging that the purpose of a university to-day is to make youth fit and eager to render professional service to their fellow citizens, not simply to sharpen wits but to build character, seemed to put into different words much that Prof. Gray said in his inaugural lecture. It is undoubtedly a fundamental question, and the answer we give to it may well determine that to be given to the various questions arising as to how and where university expansion should take place—the character as well as the size of university institutions, the scale on which they are to be equipped with halls of residence and libraries, the balance between research and teaching, and the ratio of staff to students as well as the content of courses and the standards of admission. Unless clear and considered answers are given to such questions, university expansion is unlikely to proceed at the necessary speed without seriously endangering standards.

The debate in the House of Lords showed that these problems are recognized rather than that acceptable answers to them have been found. Lord Simon of Wythenshawe proposed specifically to refer some of them to a special committee of inquiry or even to a Royal Commission to consider the needs of the next twenty years, and meanwhile to instruct the University Grants Committee to proceed with its present plans. Lord Beveridge similarly pleaded for a special, impartial study of such questions as the number of university students at which we should aim, the size of particular universities, the emphasis on research, the method of selecting students, the relation of university education to other advanced education for adults in Britain, and the study of university methods outside Britain and the changes of social conditions and their effect on university life. There seemed to be some general agreement in the debate that expansion in the main must fall upon the more modern and younger universities or by the creation of new institutions, though it was also recognized that some regard must be paid to the expansion of technological education; indeed, it was a feature of the debate that the contribution to higher education made outside the universities was so strongly stressed.

Lord Dalton strongly urged that university matters should be kept outside the Ministry of Education; Lord Adrian advocated making the Minister of Education responsible for all education, university and technological, as well as technical and primary and secondary, though he did not want to see the Ministry take over the functions of the University Grants Committee, and in this he had strong support from Lord Pakenham. Indeed, he suggested that we must be rather careful that in planning extensions in technological education as well as in other fields of higher education we do not set up an organization which would threaten the independence of the universities, and he himself supported the idea of an independent inquiry quite apart from the problems of university expansion.

No one was more emphatic than Lord Bridges that the main point calling for inquiry to-day is what we should expect to get from the universities in quality rather than in quantity. With such an inquiry into what the nation and the professions could expect and look for from those who have finished a university education could go a parallel inquiry into the rate of expansion in the universities and the way that expansion is carried out, including the processes by which new universities are established, their location and the idea of a regional university. Lord Esher, who was highly critical of the present university graduate, urged the importance of giving change and variety to the pattern of university life, and Lord James of Rusholme, too, believes that many of the present university courses designed to produce scholars in a narrow field rather than for the education of those with no genuine pretensions to scholarship may not be the most suitable we could devise. There is something to be said, he believes, for continuing work in general education, and it is right that we should demand not only technical skill and new knowledge but also those judgments of value which can illumine the life of the whole community. Viscount Caldecote made a similar point in suggesting that our selective system is so efficient that it is widening a dangerous gulf between those who go to a university and those who do not. He, too, emphasized the increasing importance of a broad education as science takes a larger place in our lives, if science is to be our servant and not our master; and he is specially concerned at the effects of premature specialization and of paying excessive attention to the passing of examinations to the detriment of broad education. He believes that the most important question that requires examination at the moment is the effect of university policy on education in the schools.

There was other authoritative support for a fresh look at the relation between education in the universities and in the schools, and at the distribution of effort between research and teaching in different universities, for example, from Lady Wootton of Abinger; but it was noticeable that neither of the Government spokesmen, the Earl of Dundee, early in the debate, or Lord Hailsham, in concluding, touched on this question of the purpose of education. Lord Hailsham, indeed, admitted that democracy and parliamentary government and the preservation of freedom require an adequate supply of graduates if they are to function to-day—this is a matter not merely of quantity but equally of quality. Nor did Lord Hailsham limit his view of graduates to those coming from the universities alone.

Lord Hailsham's speech was of interest chiefly for what he said about the basis on which the Government has laid its plans for university expansion in Britain. It is estimated that, apart from the nine colleges of advanced technology with some 9,000 full-time students, existing universities and university colleges had roughly 101,000 full-time students in October 1959 and will have by 1965–67 some 135,000; apart from any places that may then be available in the proposed new universities at York, Norwich or elsewhere. First, Lord Hailsham emphasized that, at least up to 1970, the difficulties will lie in finding places for the talent that will be available for the schools. In the light of this knowledge, the universities have discussed with the University Grants Committee how far and fast they can expand, and the possibility of further expansion from 135,000 to 170,000 places is now being explored. It is believed that this can be achieved without detriment to academic traditions and standards by expansion at the existing universities, with a contribution from new universities. Thirdly, the Government has examined separately the problem of meeting the need for scientists and technologists, and by 1970 the universities should be producing rather more than half the 20,000 required; some 10,000 would come from the colleges of technology. The probable demand for school teachers during the next fifteen years has also been studied, and it has been decided to provide a further 25,500 places in teacher-training colleges.

Lord Hailsham reiterated the Government's desire to maintain the academic independence of the universities themselves in spite of their increasing dependence on Government finance, and its firm support of the University Grants Committee as the means for preserving such autonomy. He did not exclude the possibility of an independent appraisal of the whole situation, and more especially of questions of curriculum in both schools and universities, though in any such inquiry he would like to see due account taken of the views of the Advisory Council on Scientific Policy. Especially he stressed the desirability of satisfying ourselves that the present arrangements for co-ordination between the universities and other places of higher education are adequate, and that we have an organization between the University Grants Committee and the Ministry of Education capable of dealing with questions that might arise as to the allocation of resources between the universities and the colleges of technology. Lord Hailsham promised that the Government would consider very carefully the points of view that had been put forward in the debate, and would seek the best possible means of giving effect to them.

As Lord Simon recognized, more could not be expected; but it is clear that the discussion on the purpose of a university education, its content, and where it should be given and to what proportion of the population, is only beginning. Until those questions, however, are answered, no firm decisions can be taken as to the proportion of our resources to be expended on higher education, let alone its distribution.

FUTURE OF BRITISH AGRICULTURE

Principles for British Agricultural Policy

A Study sponsored by the Nuffield Foundation. Edited by H. T. Williams. Pp. xiii+317. (London: Oxford University Press, 1960. Published for the Nuffield Foundation.) 18*s*. net.

AGRICULTURE differs so completely from other industries that none of the ordinary rules seem to apply. It is carried on by individuals and not by limited liability companies, its units are small compared with those of commercial enterprises, its risks cannot in general be estimated and covered by insurance, and its financial rewards are on a much lower level than those of most other business activities. But it plays so vital a part in the life of the nation that it has to be kept efficient in good times and bad. In 1945 the Nuffield Foundation set up a small committee to formulate the principles on which a stable agriculture could be based capable of producing in time of peace enough food to avoid heavy imports, and in time of war expanding sufficiently to save the nation from starvation. The committee included among others Sir Frank Engledow, Sir Geoffrey Crowther, the President, Vice-President and Secretary of the National Farmers' Union. The first draft of its report was ready in 1951, and preparations for the second, the present volume, began in 1956: the effect of the long delay shows itself in some unevenness in the dates of the statistics but it does not appear to have adversely affected the text.

The book opens with an account of the vicissitudes of British farming from 1840, when the abolition of import duties on corn led to unrestricted competition from the newly developing countries which finally reduced British agriculture almost to bankruptcy in the 1890's. Some recovery followed, but by 1931 the experiences of the First World War and the 1920's had shown that a different type of treatment was necessary if the industry was to survive in any efficient way. The first efforts had little success; by 1939, when the Second World War began, only about 30 per cent of the nation's food (measured in calories) was being produced at home. Vigorous government intervention stimulated greater output during the war but at enormous public expense: the maximum increase was about 50 per cent in net output, but 70 per cent in calories, and it took four years to accomplish.

After the War it was realized that the provision of food for the nation was too important a matter to be left entirely to the play of international markets, and in 1947 an Act was passed with the object of giving agriculture a stable economic basis and directly encouraging efficiency in production. The method adopted was to help farmers in carrying out improvements in methods and to assure for all listed commodities a market at guaranteed prices arrived at by negotiations between the National Farmers' Union and the Ministry of Food and Agriculture. This involves a good deal of public expenditure, amounting now to about £250 million per annum, but it is achieving results, and the present output is some 30 per cent higher than the war-time peak, 68 per cent higher than pre-war, and still rising. The Committee thinks a further rise of 60 per cent is possible; the methods proposed include an extension of ley farming, drainage, and larger use of fertilizers and lime.

The justification for so much public assistance is discussed from the social, economic and strategic points of view. The social case is not very strong: there is no evidence that home-grown food is more nutritious than imported, though in so far as it is fresher it may be more tasty. Country life is healthier than town life and the surroundings are pleasanter, but the differences are lessening as urban health improves and the beauty of the countryside is increasingly despoiled. More might have been made of the call of the land that keeps many in the country who know they could earn far more in the towns, and the fact that 80 per cent of our farmers are farmers' sons and that 40 per cent of their sons are going in for agriculture. The economic consideration is that higher food production at home protects the balance of payments; indeed the ingenious suggestion is put forward that our growing industries will require such large imports of raw materials that there may be insufficient money left to pay for large imports of food. But the strongest considerations in favour of continued government support are strategic. Agriculture should be so efficiently equipped and directed that it could in one season switch over from peace-time to war-time farming, and, for guidance to this end, that investigations should be started to discover the minimum diet under siege conditions. Storage of a year's supply of food, of tractor fuel, and of farm appliances is suggested.

The book covers much new ground, raises many points for useful discussion, and will be helpful to all concerned with agricultural administration. It will be particularly interesting to the large number of people who are beginning to wonder whither British agriculture is tending.

E. JOHN RUSSELL

IN PURSUIT OF WORLD HEALTH

World Health

By Fraser Brockington. (Pelican Book No. A425.) Pp. 405. (Harmondsworth, Mddx.: Penguin Books, Ltd., 1958.) 5s.

TO write a book on world health which is directed to "all who are interested in the health of the world" would seem a boundless undertaking. Prof. Brockington takes a wide view of his assignment—those with a special interest in the more technical problems of the organization of health measures throughout the world might deem too wide. But if one accepts, in line with the author's argument, that a necessary ingredient of health policy is the understanding and co-operation of the people affected, that the promotion of better health depends on rousing the interest and enthusiasm of politicians, specialists and the public in general, then he has written the right kind of book. He ranges widely, he illustrates richly, he provokes and stimulates by the skilful use of example and statistics, he communicates enthusiasm.

Health is essentially a social concept and the pursuit of public health involves one, as Prof. Brockington interprets it, "not only in technology, but also in philosophical, anthropological, organizational, social and economic considerations". After a brief discussion of the meaning of health and disease and a sketch of the picture of disease throughout the world, he discusses the social framework and its relation to health and disease. In only some hundred pages he carries one through a consideration of geography, of beliefs and customs, of family life, of population, of occupation, of town life, of hospitals, of food, of industrialization. Points are made rather than theories developed—he relies on the piquant example and the vivid detail. Tuesdays and Fridays, one learns, are special days for treatment in Peru as they are magically favoured. 'Spitting forbidden' is not a universally acceptable maxim: the restriction against spitting tobacco juice on the walls had to be withdrawn before the maternity home gained favour in one African township. But should there be disappointment with the brevity of the treatment, he provides for this section a particularly lengthy and wide-ranging list of references. (The whole bibliography is indeed an excellent and most useful compilation.)

The sections on public health practice throughout the world and on international public health give a rapid survey of the organization of public health in different areas and at different times and lead up to a review of the first ten years of the World Health Organization. While recognizing the difficulty of finding any set of common principles for the practice of public health, Prof. Brockington proffers five for consideration: "the inseparability of preventive and curative medicine", "the primacy of preventive medicine", "unity of control", "co-ordination" and "local government and participation by the people". These would seem to add up to the philosophy which runs through the book and to the view of public health which Prof. Brockington seeks to propound. He looks back with approval on Chadwick, who whipped nineteenth-century England along the right road, and cites, as an example of an effective modern policy, Yugoslavia which "wiped the slate of past endeavours clean" and under the wise guidance of Prof. Stampar recognized the importance of the local health unit and based its health services on the health centre and the institute of hygiene.

In the final section, on the measurement of health, Prof. Brockington deals with health statistics and the problems of collecting and recording data. It is enlivened by shrewd comment and timely cautions; but, being both too brief to serve as an adequate introduction to the subject and too sketchy to be useful as a text-book, one wonders whether the more technical material might have been included more usefully as an appendix. It has its place in a comprehensive book on world health, but it is in a different key from the discussion of wider, more general issues, and follows awkwardly on a plea for better international understanding through the common pursuit of health. Certainly for the non-medical reader it is not as a text-book but as, in the best sense, propaganda, that this is such a very stimulating and interesting book. CHRISTINE COCKBURN

CLASSIFICATION OF THE CESTODES OF VERTEBRATES

Systema Helminthum

By Prof. Satyu Yamaguti. Vol. 2: The Cestodes of Vertebrates. Pp. vii+860. (New York: Interscience Publishers, Inc.; London: Interscience Publishers, Ltd., 1959.) 90 dollars; £34.

THE second volume of Satyu Yamaguti's "Systema Helminthum", which deals with the cestodes, conforms in plan with the preceding volume dealing with the digenetic trematodes. Essentially, the book is a compilation of diagnoses of 55 families, 43 sub-families and 466 genera of cestodes, arranged in five parts according to the classes of vertebrate hosts. Specific names are also listed for the genera, and there is a brief "Systematic Survey" bringing together all the taxonomic units used down to genera, which is followed by 2,427 references to the original literature, 584 illustrations grouped in 70 plates, and an index taking up rather more than 90 pages of two columns each. Some of the criticisms applied to the previous volume[1] apply also to this one. The arrangement of the diagnoses under the headings of hosts—fishes, amphibians, reptiles, birds and mammals—will be convenient to some users of the book, but others will be dismayed to find the data for genera and species dispersed for any family which has representatives in two or three classes of hosts.

An orthodox scheme of classification is adopted. Cestodes are arranged in two unequal subclasses, the Cestodaria (3 orders, 4 families, 9 sub-families and 31 genera) and the Eucestoda (10 orders, 51 families, 34 sub-families and 435 genera). The orders of non-segmented cestodes (Cestodaria) are named Amphilinidea (2 families), Gyrocotylidea (1 family) and Caryophyllidea (1 family). The orders of strobilate cestodes (Eucestoda) are named Pseudophyllidea (9 families), Aporidea (1 family), Cyclophyllidea (15 families), Diphyllidea (1 family), Lecanicephalidea (5 families), Nippotaeniidea (1 family), Proteocephalidea (1 family), Spathebothriidea (3 families), Tetraphyllidea (4 families) and Trypanorhyncha (11 families). There is also a list of 12 genera incertae sedis, 8 occurring in fishes, 2 in birds and 2 in mammals.

This inequality of the orders of cestodes in respect of families extends also to families in respect of sub-families and genera. 43 out of 55 families do not require sub-families and these contain 152 out of a total of 466 genera. 15 of the 43 families contain one genus, 9 contain two genera and 7 contain 3 genera, while the remaining 12 families contain altogether 98 genera, 4–18 per family. 4 of the 12 sub-divided families have two sub-families (14 genera), 3 have three (112 genera), 3 have four (96 genera), 1 has five (58 genera) and 1 has nine sub-families (22 genera): thus, 12 families contain all the sub-families involved in the classification of the Cestoda and a total of 302 genera. Notably, the Hymenolepididae contains 83 genera, the Dilepididae 73 genera and the Anoplocephalidae 58 genera. These families belong to the Cyclophyllidea. Next in this descending order come the Proteocephalidae and the Caryophyllaeidae with 23 genera each, and the Phyllobothriidae with 20 genera.

Cestodes are also unequally distributed in the classes of host; 37 families are represented in fishes, 4 in amphibians, 6 in reptiles, 16 in birds and 10 in mammals. However, only 42 families of cestodes are represented solely in one class of host, 33 families in fishes, 1 family in amphibians, 6 families in birds and 2 families in mammals. No family is represented in reptiles alone. Thus, 13 families of cestodes occur in two or more classes of hosts, and there are 31 overlaps between the classes, 4 involving fishes, 3 amphibians, 6 reptiles, 10 birds and 8 mammals. Families represented in two classes of host number 1 in fishes and reptiles, 1 in fishes and birds, 1 in amphibians and reptiles, and 5 in birds and mammals. Families represented in three classes of hosts number 1 in fishes, amphibians and reptiles, 1 in fishes, amphibians and birds, and 3 in reptiles, birds and mammals. In contrast with the findings for the digenetic trematodes, not one family of cestodes is represented in all classes of vertebrate hosts, or even in four out of five of them.

In his introduction, Yamaguti mentions previous work dealing with particular groups of cestodes or with cestodes of particular geographical regions. He also pays a tribute to the book "The Zoology of Tapeworms", by Wardle and McLeod (1952), the only other book dealing with cestodes on a world-wide scale. It will be useful therefore to note, so far as space permits, how the taxonomic arrangements made by Yamaguti compare with those made by Wardle and McLeod. Notably, the Caryophyllidea is restored to the Cestodaria and the Biporophyllidea is abandoned, because based on a form which is indubitably a detached proglottis of some strobilate cestode. In both schemes the Eucestoda contains 10 orders, but there are major changes which seem reasonable. Yamaguti does not uphold the Disculicipitidea, referring its type family to the Lecanicephalidea, from which the Echinobothriidae is removed to stand as the solitary family of the Diphyllidea, which did not occur in Wardle and McLeod's scheme. The Pseudophyllidea has 7 families common to both schemes, but the name Diphyllobothriidae replaces the name Dibothriocephalidae, and two new families are added, the Cephalochlamydidae (2 genera) and the Parabothriocephalidae (3 genera). The order Aporidea, with its single family the Nematoparataeniidae, is retained. 13 families of the Cyclophyllidea are common to both schemes, but Yamaguti does not uphold the Biuterinidae; instead, he places the three genera (*Biuterina*, *Deltokeras* and *Cyclorchida*) for which Meggitt established the family in the Dilepididae, the first two genera in the Paruterinae and the third genus in the Dilepidinae. *Neyraia* (Syn. *Biuterinoides*) is also placed in the Dilepididae (Paruterinae). Included also in the Cyclophyllidea is the family which I will call the Progynotaeniidae Fuhrmann, 1936, emend. Burt, 1939, formerly standing in the Acoleidae, and the new family Triplotaeniidae made for *Triplotaenia*, which Wardle and McLeod placed in the Anoplocephalidae.

In the order Lecanicephalidea Yamaguti retains the Lecanicephalidae, after abstracting *Tetragonocephalum* and making it the type genus of a new family, the Tetragonocephalidae. He also makes *Parataenia* a synonym of *Polypocephalus* and rejects the family Cephalobothriidae, in which Wardle and McLeod placed the latter genus, placing *Cephalobothrium*, *Hexacanalis*, *Tylocephalum* and *Calycobothrium* in the Lecanicephalidae, and making *Adelobothrium* the type genus of a new family, the Adelobothriidae. As already stated, the Disculicipitidae is also added to the Lecanicephalidea, and another added family is the Balanobothriidae, erected by Pintner for *Balanobothrium*, which Wardle and McLeod placed in the Tetraphyllidea! Yamaguti has retained the Nippotaeniidea (1 family) and also the Proteocephalidea, which also has only one family but, thanks largely to the work of Mola and of Woodland, 7 sub-families, to which the Prosobothriinae is now added to contain *Prosobothrium* (Syn. *Lintoniella*). Wardle and McLeod placed "*Lintoniella*" in the Proteocephalidea (Proteocephalidae) but *Prosobothrium* in the Lecanicephalidea (as a genus inquirendum)! The order Spathebothriidea is retained as founded by Wardle and McLeod, and the two large families of the order Tetraphyllidea with comparatively few changes, although *Tetracampos* is removed, regarded as a synonym of *Polyonchobothrium* and placed in the Pseudophyllidea. *Myzophorus* is also removed and placed in the Proteocephalidea. Two new families are added to the Tetraphyllidea for genera not mentioned by Wardle and McLeod, namely the Triloculariidae and the Maccallumeiollidae. Finally, Yamaguti upholds the ten families of the complex order Trypanorhyncha, which is divided into the sub-orders Cystidea (8 families) and Acystidea (3 families); included in the Cystidea is the family Hornelliellidae erected by Yamaguti in 1954.

It would be beyond the scope of this review to enter into further details. Let it suffice to say that Yamaguti's sterling attempt to correct many errors of judgment which appear in "The Zoology of Tapeworms" will be received gratefully by many parasitologists. They may not agree with his scheme in its entirety, but will have to admit that it is a step in the right direction. The illustrations are better than those of trematodes in the previous volume, although some of them are too small to be serviceable. That part of the "Systema Helminthum" which deals with the flat-worms (Platyhelminthes) is now complete. Unfortunately, it is not a text-book and therefore morphological details are diagnostic and incomplete. But the task of arranging about 3,290 species of cestodes (discounting about 560 names which include synonyms, varieties, renamed species, etc.) and 4,934 species of digenetic trematodes (discounting about 333 names of synonyms, etc.) in a taxonomic scheme has been achieved. Families in the Cestoda and the Digenea number respectively 55 and 102, sub-families 43 and 355, and genera 466 and 1,024, respectively. Both groups are predominantly parasitic in fishes and the Digenea show the greater degree of spreading into other classes of vertebrate hosts. For the assembly of this enormous amount of scientific data Yamaguti has richly earned the gratitude of an army of research workers in the field of parasitology.

BEN DAWES

THE PRESENT POSITION IN LEATHER SCIENCE

The Chemistry and Technology of Leather
Edited by Fred O'Flaherty, William T. Roddy and Robert M. Lollar. Vol. 2: Types of Tannages. (American Chemical Society Monograph Series, No. 134.) Pp. xiv+554. (New York: Reinhold Publishing Corporation; London: Chapman and Hall, Ltd., 1958.) 132s. net.

LEATHER science is not amenable to easy presentation in text-book or treatise form. Many of the problems of practical importance to the industry are of such complexity that only empirical results exist, which different investigators have attempted to link together by plausible hypotheses. It is not possible to decide between rival hypotheses using the available data, so that differing views have in some instances continued to exist side by side over long periods, with fluctuating popularity. In contrast, topics where scientific progress has been greatest—the composition and structure of collagen; the structure of vegetable tannin materials—can only with difficulty be related to practical problems facing the industry to-day.

This uneven development of the subject is reflected perhaps more sharply in the second than in the first of the four volumes on "The Chemistry and Technology of Leather", entitled "Types of Tannages", which F. O'Flaherty, W. T. Roddy and R. M. Lollar are editing for the American Chemical Society Monograph Series. Vegetable tanning and chrome tanning are each considered in three chapters, one concerned with the chemistry of the tanning agents, a second with the mechanism of tannage and the third with the industrial process. While T. White ably summarizes critically the extensive structural research on vegetable tannins, a comparable critical account is not achieved by T. C. Thorstensen in his chapter on the chemistry of chromium salts. The chapter by E. B. Thorstensen on the practice of chrome tanning is also inadequate, which is especially unfortunate in view of the present importance of chrome tanning processes in the industry.

The treatment of other tannages varies according to the interests of the author. A. Kuntzel, in his account of oil tanning (chamois leather), draws on literature from all over the world. In contrast, G. A. Butz, in considering combination tannages, concentrates on the production of U.S. Army 'Retan' leathers. He includes a number of detailed manufacturing processes, whereas some other authors exclude these. Each of these two chapters is valuable in itself, but they do not stand easily side by side in a single book.

The rapid development of zirconium tannage has already somewhat outdated I. C. Somerville's clearly written account. Other chapters are concerned with aldehydes, alum and iron tanning, the use of silica, polyphosphates, replacement synthetic tans, resin tannage and sulphonyl chloride.

Three general chapters are included in the volume. Y. Nayudamma gives a useful summary of shrinkage temperature measurements and their significance, while L. Seligsberger and C. W. Mann draw on their experience at the U.S. Quartermaster Research and Engineering Center, Natick, Mass., to discuss stability of tannage. This chapter is especially valuable as the subject has been neglected by other books on leather.

---

[1] Dawes, B., *Nature*, 183, 957 (1959).

R. M. Lollar's opening chapter on the criteria which define tannage, illustrates the difficulties of drawing general conclusions, and of summarizing so varied a subject.

Much of the book is of too technical a character to interest chemists other than those concerned with the production and use of leather. For leather chemists, it provides useful summaries of certain fields, but in others, requires cautious study, and in a third, smaller, group of subjects, it gives only an inadequate account. Students will not easily use it, except for reference, and even there its usefulness is limited by the need to read critically. In this respect, the second volume falls short of the first, where several chapters, while providing adequate reviews, were also excellently adapted to student use.

A. G. WARD

THE NEWER METALS

Tantalum and Niobium

By Dr. G. L. Miller. (Metallurgy of the Rarer Metals, No. 6.) Pp. xxii+767. (London: Butterworths Scientific Publications; New York: Academic Press, Inc., 1959.) 120*s*.; 21 dollars.

Analytical Chemistry of Titanium Metals and Compounds

By Maurice Codell. (Chemical Analysis: a Series of Monographs on Analytical Chemistry and Its Applications, Vol. 9.) Pp. xiii+378. (New York: Interscience Publishers, Inc.; London: Interscience Publishers, Ltd., 1959.) 90*s*.

The Chemical Behavior of Zirconium

By Warren B. Blumenthal. Pp. vi+398. (Princeton, N.J.: D. Van Nostrand Company, Inc.; London: D. Van Nostrand Company, Ltd., 1959.) 82*s*. 6*d*.

COMPARATIVELY recent improvements in the techniques of extraction metallurgy have given, in effect, new metals for old. The higher degrees of purity now attainable, and in particular the much greater control over oxygen, nitrogen and hydrogen contents, have with several metals caused brittleness to be replaced by an attractive ductility. This, and the constant search for metals capable of withstanding ever more stringent conditions of service, accounts for the considerable amount of research and development work now in progress on metals such as niobium, tantalum, titanium, and zirconium, with which the three books under review are concerned.

In his book "Tantalum and Niobium", Dr. G. L. Miller has followed the general pattern of his earlier volume, "Zirconium", in the same series. Most of the available data on niobium and tantalum are presented in a systematic manner and generally in considerable detail. About a third of the book is devoted to the extraction and consolidation of the metals, another fifth to the known binary equilibrium diagrams, and a seventh to behaviour of the metals under corrosive conditions. The role of niobium and tantalum in steels and in heat-resisting alloys is dealt with less fully, and reference is made to a monograph on the subject.

Many line diagrams and half-tone plates are used to illustrate the text and apart from a few printing errors the book is well produced.

During the past five years there has been a considerable increase in the effort devoted to the refractory metals and their alloys, and it seems likely that this book has been produced just before the results of many of the newer investigations are published; a second edition may be required at a relatively early date. In the meantime, the volume will be a useful reference book for those concerned with the production of niobium and tantalum, and with research into their properties.

Realization of the importance of minor impurities, and the development of titanium from a scientific oddity to a metal of technological importance has brought with it many analytical problems. In his book on "Analytical Chemistry of Titanium Metals and Compounds" Maurice Codell has provided a comprehensive account of modern methods. About 100 pages are devoted to the chemistry of titanium and general analytical procedures, including spectrographic, vacuum fusion, polarographic and spectrophometric techniques, 200 pages to the analysis of titanium and its alloys, and 70 pages to the analysis of titanium-bearing pigments, ores and slags.

Experimental detail is clearly presented, and the lay-out is such that the book may conveniently be used as a laboratory handbook. Within this volume any competent analyst should find the information and guidance that will enable him to deal with any analytical problem relating to titanium which he is likely to encounter. It is unfortunate that in a book of this kind there should be no details of reproducibility of the analytical results for titanium and titanium alloys. In this respect the author is inconsistent, since he gives details of accuracy of some spectrographic and vacuum-fusion methods. It is to be hoped that in any future edition he will provide this kind of information more generally throughout the book, for it would add greatly to its value and help readers to select the analytical technique most suitable to their purpose.

In his preface to "The Chemical Behaviour of Zirconium", Warren B. Blumenthal writes that it was his intention to provide students and research workers with a broad and detailed account of the chemistry of zirconium as an element and as a component of compounds, interstitial solutions and alloys. The space devoted to alloys is so small that the author can scarcely claim to have dealt with this branch of his subject. It is therefore in regard to his other objectives that the book should be judged.

The text is supported by numerous references, and the reader should be able to find the available information on the reactions of zirconium compounds. One difficulty in presenting knowledge on zirconium compounds arises from the lack of conclusive data on the structures of ions and compounds of zirconium. This leads to the presentation of a large number of structural models without the sound experimental backing usually found in other fields of inorganic chemistry. It also enables the author to point out several fruitful fields of study for chemists interested in the structure of inorganic compounds.

The author's claim that " . . . the basic rules are presented that govern the properties of zirconium and its compounds" is scarcely justified. The immense amount of information presented is largely in the form of detailed accounts of the reactions of zirconium compounds without emphasis on the underlying electronic principles. It may be that at this stage a satisfactory and systematic treatment is not possible because so much more experimental work is required before the reactions discussed by the author can be properly understood and correlated. He would probably have been wise to make less ambitious claims for his book, and to put it forward as a record of what is known about zirconium compounds, recognizing the limitations that are imposed by writing at this relatively early stage in the development of the subject.

A. G. QUARRELL

EVOLUTIONARY THEORY AFTER MENDEL

Genetics and Twentieth Century Darwinism

(Cold Spring Harbor Symposia on Quantitative Biology, Vol. 24.) Pp. xv+321. (Cold Spring Harbor, New York: Long Island Biological Association, 1959.) 8 dollars.

BETWEEN an introduction by E. Mayr, surveying the contemporary aspects of evolution, selection and speciation and a concluding synthesis by G. L. Stebbins, which is partly based on the twenty-two contributions by the participants in the symposium, this volume contains a good deal of factual information from many fields. While the general and qualitative conclusions of the specialists are on the whole remarkably uniform and furthermore similar to concepts which Darwin himself held a century ago, one is struck by the vastly greater extent and certainty of our knowledge and also by the superior techniques and quantitative methods which are employed in gaining this knowledge.

The only fundamental difference between our approach and that of Darwin stems from our recognition of particulate and chromosomal inheritance as the basis of much of hereditary variability upon which selection and isolation act; and thus mutation and gene recombination—processes of which Darwin was of necessity ignorant—play very prominent parts in our ideas of evolution. Genes as raw materials of evolution are considered by Dobzhansky, Stubbe and Buzzati-Traverso, while race formation by selection is described by Morley and by Schwanitz in plants, by Mourant (blood groups), Barnicot (climatic influences) and Coon (other ecological factors) in man and by Lamotte in snails. Genetical conditions conducive or refractory to race formation are described by Carson. The interplay between ecology and genetics in the evolution of mimicry is expounded by Sheppard; the differentiation–hybridization cycle and polyploidy in *Achillea* by Ehrendorfer.

Speciation and isolation are described by Kitzmiller and Laven in mosquitoes and by Baker concerning flowering plants. Wallace analyses the influence of genetical systems on geographical distribution.

In addition to those contributions, which deal with evolutionary processes still at work, there are four papers concerning the fossil record and evolutionary rates in early vascular plants (Andrews), mammals (Kurten), fossil (Heberer) and contemporary (Hunt) man. A final rather heterogeneous group of papers, headed "Trends of Evolution", deals with the nature and origin of supraspecific taxa (Simpson), the chromosome evolution in the Australian flora and the progress in the brain and sense organs of animals (Rensch).

As usual in the Cold Spring Harbor series, the individual papers are followed by selections from the discussions in which, in addition to the contributors, a wider circle of listeners participated.

Like its predecessor on the "Origin and Evolution of Man" (1950) the present symposium included geneticists, anthropologists and palæontologists, to which, however, ecologists were added. This fourfold attack resulted in a broader grasp of the subject of evolution: in revealing the existence of considerable gaps and blurs between the descriptions it also shows where further work is needed.

The volume is well produced, illustrated and documented, and I have noticed only one editorial mistake: a completely wrong title in the contents of the paper on p. 115.

H. KALMUS

THE EXPLODING WIRE PHENOMENON

Exploding Wires

Based on Conference on the Exploding Wire Phenomenon, April, 1959, conducted by Geophysics Research Directorate, Air Force Cambridge Research Center, with the co-operation of Lowell Technological Institute Research Foundation. Edited by William G. Chace and Howard K. Moore. Pp. 373. (New York: Plenum Press, Inc.; London: Chapman and Hall, Ltd., 1959.) 76s. net.

CURRENT interest in thermonuclear projects, in high-speed photography, and in phenomena associated with shock waves has provided a powerful stimulus to research on exploding wire phenomena. It is a disappointment to find that the first book on this subject, described by the publishers as a significant monograph, is only a collection of papers presented at a conference, with no index, no record of the discussions, and the minimum of introduction. Apart from the stiff binding and the high quality of the illustrations, the arrangement of the material which has been adopted, putting the diagrams at the end of each paper, and the photographic reproduction of the text, cause this volume to resemble the preprint of a conference rather than an authoritative work.

Some of the papers presented are excellent; but the general emphasis is on experimental methods rather than on results. Roughly half the twenty-five papers presented deal with the use of techniques such as voltage and current oscillography, high-speed photography and radiometry in studying the explosion of wires by condensers storing energies between one and one million joules. Of particular interest are papers dealing with the 'dwell time' between the initial current pulse and the build-up of the main discharge, and Scherrer's elegant work with a water-dielectric condenser. The remainder of the volume is evenly divided between theory and application. In the former category there are three useful papers on cylindrical shock waves; the applications include flash sources for photochemistry, the bonding of nonconductors, plasma acceleration, and as fuses to protect condenser banks.

While this volume will be of value to workers in the field, it is neither sufficiently correlated nor comprehensive enough to be a good, balanced account of the subject. It would have been greatly improved by the inclusion of a long introduction describing the previous work in the field, particularly that of Anderson and Nagaoka and recent Russian contributions. Some unnecessary illustrations, such as the three successive pages of pictures of somewhat pedestrian electronics, could well have been omitted. It is not easy to see why these papers have been collected in a single, highly priced volume, when they could have been published in a scientific journal.

B. A. Thrush

A STUDY OF NON-LINEAR PROBLEMS

Nonlinear Problems in Random Theory

By Prof. Norbert Wiener. (Technology Press Research Monographs.) Pp. ix+131. (Cambridge, Mass.: Technology Press of the Massachusetts Institute of Technology; New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1958.) 36s. net.

This is a collection of lectures reproduced by participants of a course given by Prof. N. Wiener at the Massachusetts Institute of Technology. The lectures were recorded by means of a tape-recorder and thus the volume includes the author's spoken words; photographs of formulæ actually written down on the blackboard are reproduced. The resulting informal style fits very well with the contents; there is a wealth of ideas and suggestions, both on theory and applications, but the mathematical reasoning is often somewhat incomplete.

The book deals with non-linear functionals of the sample functions $x(t)$ of a stochastic process, which for the most part is the Brownian motion (Wiener) process. Starting with a description of that process, the author then studies certain homogeneous 'polynomial' functionals $F_n(x) = \int \ldots \int K_n(t_1, \ldots, t_n) dx(t_1) \ldots dx(t_n)$ and their expectations. With the help of an orthogonalization process, which makes such homogeneous functionals of different degree orthogonal to each other, a theory of expansions of arbitrary functionals in terms of homogeneous ones is developed. This is the main tool for the evaluation of the autocorrelation function and the spectrum of special functionals suggested by some applications. Frequency modulation problems, for example, lead to functionals of the type $\exp(i\int \ldots \int f(t + \tau_1, \ldots, t + \tau_n) dx(\tau_1) \ldots dx(\tau_n))$. Comparing the computed spectrum with the spectrum observed in electroencephalography, the author offers as a model for the generation of brain-waves' certain non-linear oscillators excited by a random input. The same methods are used in the discussion of the analysis and synthesis of non-linear networks, where the author first gives reasons why it suffices, in a sense, to consider a Brownian (shot-effect) input. Here, as well as in the preceding lecture, experimental details are briefly discussed.

The author outlines in a rather sketchy way connexions between the Brownian motion process on one hand, and quantum mechanics and statistical mechanics on the other hand. He remarks that the interpretation of the square of the absolute values of the coefficients in the eigenfunction expansion of a wave-function as probabilities has never been made clear in quantum theory, and he suggests such an explanation based on a formal analogy. In his new approach to statistical mechanics, the number of particles in a region of the phase-space is considered as an additive random functional.

In two lectures on coding and decoding, discrete processes are considered instead of continuous ones, and analogies to the earlier orthogonal expansions are treated. Coding consists of representing a given time series by a certain sequence of independent and equally distributed random variables. Decoding consists of the reverse operation, where each member of the sequence is determined by the 'past' of a given time series and conversely.

As stated in the foreword, the series of monographs, of which this is the first volume, is designed to make accessible research studies which are larger in scope than a paper in a specialized journal, but less ambitious than a finished book. It certainly has made a good start.

K. Krickeberg

WEATHER RECORDS OF THE WORLD

World Weather Records, 1941–50

(U.S. Department of Commerce: Weather Bureau.) Pp. ix+1361. (Washington, D.C.: Government Printing Office, 1959.) 4.75 dollars.

A fourth volume has been added to the series of "World Weather Records," this time over the imprimatur of the United States Weather Bureau and produced in collaboration with the staff of Blue Hill Meteorological Observatory, Harvard.

The three previous volumes, due to H. H. and Miss F. L. Clayton, were published in the *Miscellaneous Collections of the Smithsonian Institution* in 1927, 1934 and 1947. These year-by-year records of monthly values of temperature, rainfall and atmospheric pressure are an essential reference for all whose work is concerned with climatic behaviour and trends. The new volume, which principally covers the decade 1941–50, has been eagerly awaited. The data, contributed by the meteorological services of more than eighty nations, refer to some seven hundred points all over the world. In this volume ocean weather ship stations in the North Atlantic and North Pacific make their appearance for the first time, as do the remote islands of Marion, Heard and Macquarie in the Southern Ocean and the stations in the Falkland Islands Dependencies in Antarctica.

Another welcome feature is a great increase in the number of places for which long records have now been made available; notable additions in the present volume are Budapest (from 1780), Toronto and Hobart (both 1841–), St. Helena (pressures 1892–), Jan Mayen Island (1921–), as well as many tropical islands, extra places in the United States, Japan and elsewhere and data for Russian stations since the Revolution. There are also long tabulations of lake-levels, river-levels, dates of freezing and thawing, etc.

This is a fat volume, but the price has been kept encouragingly modest. It is to be hoped that the series will continue in this style, that further old records which have been, or are being, homogenized will be included in future volumes, and that some day the wide gap in the world meteorological network in the South Pacific will be filled by a weather ship.

H. H. Lamb

The Second BBC Naturalist

Edited by Desmond Hawkins. Pp. 124. (London: Adprint, Ltd., 1960.) 10*s.* 6*d.* net.

"THE Second BBC Naturalist" sets out to do as "The BBC Naturalist" did—provide in permanent form a record of the British Broadcasting Corporation's wild-life programmes; but whereas "The BBC Naturalist" contained articles on wild-life in the United Kingdom, the second book has ventured farther afield—to such places as the Galapagos Islands, Africa, the Indian Ocean, etc.

"The Second BBC Naturalist" is a completely independent book. The title is misleading in that it suggests it to be the second volume of a series. However, it is not necessary to possess, or even to have seen, "The BBC Naturalist" in order to enjoy this second book.

It contains twenty-two articles on wild-life, following its introduction, specially written by such well-known naturalists as David Attenborough, James Fisher, Hans Hass, Maxwell Knight, Peter Scott and others equally as famous. Each article is very pleasantly written, and from the wide variety of subjects there should be something to interest everyone.

Each page contains at least one interesting picture or diagram, some in black-and-white, some in colour, many most unusual. There are some particularly fascinating charts showing the speed and height of bird flight, and man's visual field compared with that of the owl, the woodcock and the fish.

It is not necessary to have watched or listened to the B.B.C. programmes to enjoy this book. It is complete in itself and should find its place on the bookshelves of naturalists and laymen, children and adults.

B. J. G. Maitland

National Academy of Sciences—National Research Council

Publication No. 713: Digest of Literature on Dielectrics, Vol. 22, 1958. Pp. xiii + 293. (Washington, D.C.: National Academy of Sciences—National Research Council, 1959.) 5 dollars.

PUBLICATION 713 of the National Academy of Sciences—National Research Council is Volume 22 (1958) of the "Digest of Literature on Dielectrics" prepared by the Committee on Digest of Literature of the Conference on Electrical Insulation, Division of Engineering and Industrial Research, and edited by R. A. Sodermann and L. F. Frisco. The contents consist of four parts—measurements, general and theoretical, insulation, and applications—and an introduction by L. F. Frisco entitled "Trends in Research and Development in 1958". There are twelve chapters, each written by a different set of authors, and the attempt is made in each chapter to assess the overall progress in a particular field and to stress the more important achievements. Part 1 consists of two chapters, the first dealing with dielectric measurements below 100 Mc./s., measurements above 100 Mc./s., cable measurements, and books and reviews, and the second containing tables of dielectric constants, dipole moments and dielectric relaxation times. The subjects covered by the five chapters of Part 2 include conduction phenomena in solid dielectrics, ferro-electric and piezo-electric materials and ferromagnetic materials. During 1958, cadmium sulphide continued to be the most important material for studies of photoconduction. Several new ferro-electrics, mostly water-soluble organic crystals and oxide ferro-electrics, were discovered, and in the study of ferro-electricity and piezo-electricity in ceramics, the shift in emphasis was from barium titanate towards the high Curie-point materials related to lead titanate and lead niobate. Switching mechanisms in ferro-electric single crystals received considerable attention. The bibliographies on ferro-electric and piezo-electric materials, and on ferromagnetic materials, contain 339 and 500 items respectively, and illustrate the great activity in these subjects and the wide coverage of the digest articles on these topics.

Insulation properties discussed in Part 3 include those of rubbers and plastics, insulating films, insulating liquids, and ceramics. Developments in transformer insulation continued to be directed toward higher temperatures and moulded or cast insulating structures. Part 4 consists of one chapter in which a comprehensive review is given of progress in the development of capacitors, wires, cables, wave-guides and radomes. Military interest in components and systems to operate at high temperatures and in the presence of high-intensity nuclear radiation accounts for a considerable amount of the experimental work reported, but commercial interest in units to operate under more moderate conditions but with high uniformity of performance and reliability, was still very pronounced during 1958.

S. Weintroub

Crystal Chemistry of Simple Compounds of Uranium, Thorium, Plutonium, Neptunium

By E. S. Makarov. Translated from the Russian by E. B. Uvarov. Pp. iii + 145. (New York: Consultants Bureau Inc.; London: Chapman and Hall, Ltd., 1959.) 42*s.* net.

THE major part of this book consists of an account of the crystal structures of the polymorphic forms of thorium, uranium, neptunium and plutonium and of their binary alloys and compounds. Complete structural data are given where possible; unit cells and space groups, co-ordination numbers and interatomic distances are listed, together with many diagrams of the various structures, based on data published up to mid-1957. Intermetallic compounds are discussed far more exhaustively than compounds formed with non-metals; the treatment is brief and factual, with little critical discussion.

In addition, there are three chapters on general aspects of the subject. An introductory chapter deals with the relation between bond types and crystal structure; this chapter is so condensed that it is somewhat confusing and it would scarcely be suitable for a student learning the subject. There is a chapter on the atomic radii of the actinides which is simply a summary of an article by W. H. Zachariasen. The crystal chemistry is discussed generally in the last chapter as it bears on the position of these elements in the Periodic Table; this contains a list of compounds of Groups IV*a*, V*a* and VI*a*, and of the lanthanides of the same structural types as the analogous actinide compounds, which are discussed in terms of the well-known dual nature of the earlier members of the actinide series.

This book will be useful to research workers and to teachers of structural chemistry mainly as a guide

to the literature; it provides no substitute for a study of the original papers. The translation is adequate, but there are several typographical errors. There is no index; the compounds are grouped according to the position of the second element in the Periodic Table.
L. E. J. Roberts

Prehistoric Man in Europe

By Frank C. Hibben. Pp. xv+317+24 plates. (London: Constable and Co., Ltd.; Norman, Oklahoma: University of Oklahoma Press, 1959.) 50*s*. net.

NOWADAYS an author should think twice before attempting to describe the whole of prehistoric times in the compass of one volume, even when only a restricted area such as that of Europe is under consideration.

Although the first 102 pages of this book are devoted to the earliest times, one suspects that Mr. Hibben, a resident in America, has interests which lie rather in the post-mesolithic phases of the subject. It might have been wise to have asked some member of the American School of Prehistoric Research at Harvard, which has done so much to further palæolithic studies in Europe, to examine the earlier chapters, as well as the not too well selected bibliography, where the name of Movius is not mentioned and that of Hencken begins with a K, and where in some cases early works only are cited and their authors' later publications on the subject omitted. Mr. Hibben seems somewhat happier in the later part of the book where Bronze Age, Iron Age and Classical cultures are considered.

The illustrations have been kept down to a minimum, but the reason, of course, may well be one of finance; they include a charming photograph of a reconstruction of the Roman Forum in its glory. Of course, there is a lot of information given and the reading is easy, but the book cannot be said, especially as regards the earlier periods, to be a definitive work on the subject.
Miles Burkitt

The Literature of the Social Sciences

An Introductory Survey and Guide. By Peter R. Lewis. Pp. xx+222. (London: Library Association, 1960.) 28*s*.; 4.20 dollars.

ALTHOUGH this book does not claim to be more than an introductory survey and guide, it covers a wider field than its title might suggest. It is apparently intended for the administrator, the business man, the research worker and the general reader, and it also deals to some extent with library administration. On the strictly sociological side it is somewhat slender in view of its title but here and throughout it is sufficiently strong on the periodical literature to render it probable that the conscientious reader will be guided to what he requires. One exception may be noted on the historical side: the *Annals of Science* fills a place where the author recognizes that he has provided very slender cover. For the rest, it is difficult to criticize an admittedly selective compilation when the basis of selection is unknown, but it might be observed of the chapter on political science and public administration that it is surprising to find no reference to Sir Ernest Barker's works and that the section on the Civil Service omits too many important books. The style and production of the book are admirable and there is a good index.

Introduction to Symbolic Logic and its Applications

By Rudolf Carnap. Translated by William H. Meyer and John Wilkinson. Pp. xiv+241. (New York: Dover Publications, Inc.; London: Constable and Co., Ltd., 1958.) 1·85 dollars; 15*s*.

IT is a welcome sign of the times to have Carnap's book (perhaps the most comprehensive "Introduction to Symbolic Logic" in existence) made available in English at a modest price. This is something of immediate value to the student of symbolic logic, and will carry him right up to the frontier of advanced work. He will not find it easy going, but all the essentials are there. Part 1 deals with the system, and Part 2 with the application.

Broadly speaking, the subject as we know it has existed for scarcely more than a century (though its roots lie further back into history), and the reader will soon realize that the Aristotelean logic of the traditional kind only amounts to a trivial fraction of the whole domain. Strictly, to construct a system of symbolic logic is not to build up a language so much as a skeleton of a language. The bones are clothed by the interpretation of certain signs: it is this process which leads to applied logic, because of the great variety of these interpretations.

One of the objects of this discipline is to eliminate pre-suppositions—especially in geometry—which have crept in unawares, for example, in the long history of Euclid's parallel postulate. Another aim is the establishment of a powerful symbolism such as algebra enjoys. Numerous problems and examples are included.

An application of deep interest is Woodger's attempt to axiomize biology, possibly a major factor for the future development of biophysics.

The Use of Stereographic Projection in Structural Geology

By F. C. Phillips. Second edition. Pp. vii+86. (London: Edward Arnold (Publishers), Ltd., 1960.) 16*s*. net.

THE first edition of this book is well known to structural geologists and a new edition is to be welcomed. This concise and commendably inexpensive book provides geologists with a first-rate introduction to the subject. Dr. Phillips writes so clearly that what in some hands might be a formidable topic is reduced to enviably simple terms. The reader is first introduced to the principle of stereographic projection and is then shown its value as a geological tool. Dr. Phillips has not made any major changes in the text and the new edition differs only in detail from its predecessor. Recent advances are, however, noted and the bibliography has been enlarged.

The proof of the pudding is in the eating, and Dr. Phillips can quite justifiably state, as he does in his prefatory note to the second edition, that "The call for this edition proves that a concise account of these methods is an acceptable and useful addition to geological literature".

It is largely because of the work of Dr. Phillips that such methods are now more widely used by geologists than when this book first appeared. When a third edition is called for, a short review of some of the more interesting of recent applications of stereographic methods to tectonic syntheses might, in my opinion, be useful.

MICHAEL FARADAY AND THE EVOLUTION OF THE CONCEPT OF THE ELECTRIC AND MAGNETIC FIELD*

By PROF. L. PEARCE WILLIAMS
Department of History, Cornell University, Ithaca, New York

ALL forms of human activity have their myths which serve for a time to codify and crystallize ideas and methods into a tradition. When the historical conditions out of which these myths have sprung are altered, however, the myths themselves often linger on to challenge and bedevil future generations.

The myth of Michael Faraday, the strict experimentalist, is one of these. Its origins are, I think, fairly clear. The first half of the nineteenth century witnessed the creation of a whole host of new sciences. Chemistry, biology, electrochemistry, physiology, to mention only a few, were then erected into truly scientific disciplines. The birth of a new science is almost invariably accompanied by enormous enthusiasm. The new facts, or the new way of looking at old facts, which mark the beginning of a new departure stimulate waves of speculation in which the attempt is made to build overnight what generally takes decades to achieve. Many of these enthusiastic guesses may later be shown to be of real value although at the time they were ignored. A young science, however, has few criteria for the testing of general speculations. Only when the science has matured is there a 'sense of the possible' which permits the critical examination of hypotheses and the separation of the whole grain from the straw. In the nascent stage, therefore, heavy emphasis must be put upon the foundations; no matter how beautiful or seductive a suggested superstructure may be, there will be enormous pressure to ignore it (and to discourage the activities which give rise to these speculations) and get on with the more immediate task. Faraday was midwife to a number of such new sciences. His work on electrochemistry, electrostatic induction, electromagnetism, light, and the magnetic condition of matter mark the beginning of a new tradition in these studies. Faraday's more conservative and less-gifted contemporaries recognized his genius by depicting him as a foundation builder of unsurpassed skill. Here is the familiar figure of Faraday the empiricist gently coaxing from Nature the new facts upon which others could erect general theories. Here I wish to modify this picture by adding a new dimension. Faraday, the layer of empirical foundations for new sciences, is known to all; I wish to introduce Michael Faraday as a master architect, to whom new facts were the raw materials for the construction of a theoretical edifice of startling beauty and symmetry.

The concept of the field to-day underlies the whole picture of modern physical reality. The phrase 'physical reality' should be stressed, for field theory, bristling with complicated mathematical equations and dealing with the strange properties of space, seems far removed from ordinary ideas of everyday experience. It also seems out of place when the subject is Michael Faraday, self-confessed mathematical illiterate, and the epitome of self-taught common sense. Yet my purpose here is to indicate precisely how the idea of the field slowly emerged from Faraday's considerations of the nature of matter and its forces. As I shall attempt to show, the specific discoveries which earned Faraday immortality in the history of science—the laws of electrochemistry, the discovery of specific inductive capacity, the rotation of the plane of polarized light by a magnetic field, diamagnetism—were the logical deductions from an overall theory which guided him in his investigations and culminated in the concept of the field.

In a charming passage of a letter to his friend Benjamin Abbott, dated August 1, 1812, he recounts the following anecdote: "Six or seven years ago whilst standing at the door of a gentleman's house and waiting until my knock should be answered, I thrust my head through some iron railing that separated the doorway from another and then I began to consider on which side of the rail I was. In my mind I affirmed that the side possessing my head was my station for there was my perception, my senses. I had just sufficient time to ascertain this when the door opened and my nose began bleeding by the contact of the rail and such matter as that quickly put flight to my rude metaphysics. Simple as is this instance it did more in illustrating this case to me than all the arguments I have heard since on the subject, or all the affirmations that have been made".

This "rude metaphysics" was later refined in discussions with his friends from the City Philosophical Society, and Faraday seems quite early to have accepted the main points of the view first put forward by Bishop Berkeley. In essence, this philosophy rejected the idea of a separate 'matter' of which the perceptible qualities of bodies were properties. Where Locke had stated that there was something (matter) which remained when all perceptible qualities had been stripped away, Bishop Berkeley insisted that reality consisted solely of these perceptions and that 'matter' was a mere figment of the imagination.

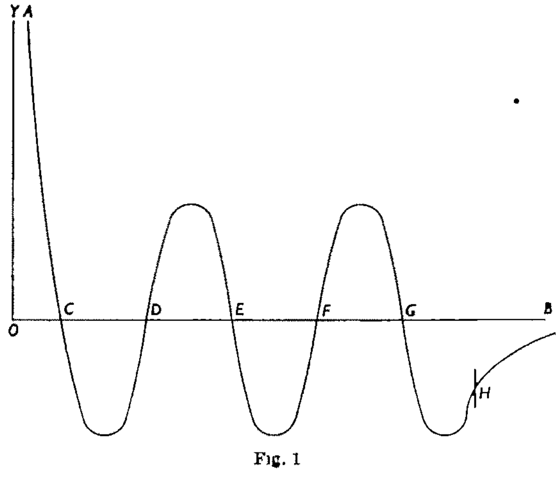

Fig. 1

---

*Evening discourse at the Royal Institution delivered on May 4.

This philosophical point of view enabled Faraday to accept an atomic doctrine which also banished matter from the world. In the eighteenth century a Jesuit, Father R. Boscovich, had, for purely physical reasons, rejected the 'billiard ball' atoms of Newtonian science and substituted point centres of force. Fig. 1 represents such an atom with its centre at O. Approaching O along OB, one follows the hyperbola of Newton's inverse square law to H, where the force becomes more steeply attractive. H marks the boundary between the macroscopic and atomic realms. From H to O, there are shells of attractive (below OB) and repulsive (above OB) force. From C, the force becomes increasingly repulsive so that no two point centres can ever coincide. Faraday himself pointed out in 1844 that this idea of an atom makes a minimum number of assumptions. We experience directly the attractive and repulsive forces of matter; we never experience 'matter' without these forces. Thus, although seemingly an extremely abstract concept, this theory of matter actually corresponds most directly with our experience of the world.

Point atoms preserve all the properties of billiard balls—impenetrability, obedience to universal attraction, extension—but have advantages that billiard balls do not. In chemistry, particularly, they could be put to excellent use. The meshing of forces to yield specific and stable compounds provided a theoretical framework for the understanding of the law of definite proportions which the clumping of billiard balls could not rival. Similarly, the theory explained changes of state, the regularity and stability of crystalline forms, and the origin of chemical qualities as the result of molecular form with considerable elegance. Faraday, it will be remembered, was trained as a chemist by Sir Humphry Davy, and Davy was a disciple of Boscovich. With Berkeley and Boscovich providing the philosophical orientation, in 1831 Faraday began those "Experimental Researches in Electricity" which by 1855 were to lead him to the concept of the field.

In 1831, Faraday discovered the induction of an electric current by a moving magnet, and almost immediately after, by another current. It was this latter phenomenon which intrigued him. Why should a current be produced in the secondary when the current ceased in the primary? The particles (and by particles Faraday meant compounds of point atoms) of the secondary, he reasoned, must be in a peculiar state induced by the current in the primary. When this current ceased, the particles returned to normal, producing a deflexion of the galvanometer needle. Such a state must be one of tension among the particles, the release of which created the observed current. The state of tension Faraday called the 'electrotonic state', and it was to take a central role in his further investigations.

The idea that a state of tension might be induced by electrical forces among the constituent molecules of bodies provided a valuable insight into the mechanism of electrochemical decomposition. How and why the chemical components of bodies in solution through which an electric current could pass should be separately obtained at the electrodes without any evidence of their passage through the solution had long puzzled people. The electrotonic state offered a possible answer. As the electrical force was applied at the electrodes, the compound molecules could be strained in tension between them until a certain critical point was reached. At that point the electro-negative and electro-positive particles of the compound would break asunder and move in opposite directions, where they would immediately meet with an oppositely charged particle from the neighbouring molecule travelling in the other direction. At any given moment the constituent particles would be passing in opposite directions but tied together constantly in chemical combination, to be released only at the electrodes.

This scheme, supported by a number of clever experiments, accounted satisfactorily for the observed phenomena. But it also had revolutionary implications. Most important of these was the denial of action at a distance which had previously been invoked to explain ionic migration. To Faraday, force was transmitted by contiguous particles and not across space. To prove this, he argued that the uniform deposition of chemical entities upon the electrodes indicated that the transmission of force was in curved lines. This could not be reconciled with action at a distance, which ought to take place along straight lines. He also hinted at a new definition of an electric current (to which, however, he refused to commit himself here). The rise and fall of the electrotonic state and the consequent transmission of force in opposite directions pleased him more than the hypothesis of one or two electric fluids, which no one had yet succeeded in detecting separate from ordinary ponderable matter. The major weakness in Faraday's interpretation was the purely hypothetical existence of the electrotonic state itself. He had deduced it from phenomena but had been unable to observe it. Its rise and collapse he felt was so rapid that the state was too evanescent to detect. This evanescence was due solely to the mobility of the molecules in solution. If the same particles could be immobilized, surely the electrotonic state could still be induced and then detected!

A piece of borate of lead which, when fluid, acted as an electrolyte, was used in the attempt to observe the existence of the electrotonic condition. When it was placed in an electrostatic field and polarized light passed through it, nothing happened. The conclusion that Faraday, "the strict empiricist", drew from this was striking. He did not conclude that the electrotonic state did not exist but that: "notwithstanding the new and extraordinary state which must be assumed by an electrolyte, either during decomposition . . . or in the state of tension which is assumed as preceding decomposition, and which might be supposed to be retained in the solid form of the electrolyte, still it has no power of affecting a polarized ray of light".

In spite of the experimental evidence, therefore, Faraday remained convinced that the electrotonic state did exist in solids. To relinquish this concept would plunge him back into the old confusion of 'electric fluids' and action at a distance. With it (even though it remained hidden from sight) he could move ahead into other areas. In particular, it provided an important clue to the mechanism of electrostatic induction. In this case, as with electrolysis, the application of electric force set up a state of tension in which the contiguous particles were deformed and polarized. Discharge through a dielectric occurred when the tension grew too great for the particles to withstand, and, with great release of energy, the electrotonic state collapsed. Almost incidentally, Faraday showed that the breaking point ought to depend on the nature of the dielectric, that is, a specific inductive capacity should exist.

Again, the passage of electric force could be accounted for without the supposition of specific fluids acting mysteriously at a distance. Experiment here could decide between the two rivals. The fundamental problem to be resolved was: Did electrostatic induction occur along straight or curved lines? With infinite patience Faraday mapped the lines of inductive force and announced triumphantly that they were curves. They must be, consequently, the result of the strain of contiguous particles.

In this masterful series of researches, Faraday had brought together a number of seemingly separate phenomena under the single law of induction. The three separate cases of metallic conduction, electrolytic conduction and disruptive discharge he had shown were reducible to the degree of strain of which the constituent particles were susceptible. Metals could take very little, so the rise and collapse of the electrotonic state was almost instantaneous; electrolytic conduction depended on the strength of chemical affinity binding the particles together, and the collapse of the electrotonic state was accompanied by ionic transfer; disruptive discharge took place when the highly strained particles, locked in their positions by the forces of solid cohesion, gave way with a snap. In each case, induction preceded conduction and conduction was viewed as the breakdown of the induced electrotonic state.

By the end of 1838, after seven years of sustained experimental and theoretical effort and with the last brick in place in his theory of electrical action, Faraday's health finally gave way. He was forced to rest, and only slowly did he recover his powers of concentration and the strength to begin a new series of researches.

The new starting point was a fairly obvious one. He had shown, at least to his own satisfaction, that electrical effects were the results of the action of contiguous particles and that electrical forces were transmitted in curved lines by means of these particles. The next step was to find out if magnetic effects, so clearly involving curved lines of force, were not also dependent upon the deformation and tension of contiguous particles. Faraday's reasoning here is exactly the same as that used in the case of electrostatic induction. Since the magnetic influence could pass through non-magnetic substances (as electrostatic forces could through non-conductors), should there not be a state of magnetic strain induced upon the particles by which the force was transmitted? To detect this state of strain he had recourse once again to a ray of plane-polarized light passed through a piece of heavy lead glass in a strong magnetic field. This time the plane of the light was rotated. Fourteen years after he had first suspected its existence, something akin to the electrotonic state had finally been detected.

Since bodies which permitted the electric force to work through them but were otherwise unaffected by electricity had been named 'dielectrics', Faraday christened substances through which the magnetic forces could work without being themselves magnetic, 'diamagnetics'. Surely, however, these bodies in which a magnetically induced strain existed could not be totally indifferent to the magnetic forces. Coulomb had claimed in the 1780's that all bodies were magnetic but, except for iron and nickel, so faintly so that any effect was almost impossible to discover. By 1845, when Faraday discovered diamagnetism, most investigators had despaired of finding the effect suggested by Coulomb. With the evidence of the magnetic susceptibility of diamagnetics before him, Faraday returned to the task, using the most intense magnetic field he could find. According to Coulomb, diamagnetics should line up along the lines of magnetic force and exhibit the same, although much weaker, polarity as iron. To Faraday's surprise, diamagnetics tried to move away from the intense parts of the magnetic field and aligned themselves across the lines of force.

Faraday had not anticipated this result (the only effect so far which had not been a logical consequence of his theoretical views) but it did not at first perturb him. As he experimented with this new effect, observed the action of many different materials in the magnetic field and attempted to account for his observations within the old framework of the strain of contiguous particles, he met with serious obstacles which were ultimately to prove insurmountable. I cannot, in the limited space available here, detail his twistings and turnings as he attempted to save the hypothesis which had served him so well. Instead, I must over-simplify the tale a bit but not, I think, with any risk of distortion of the main lines of the evolution of his thought. Let us look at the next seven years (1845–52) in the light of three questions the answers to which ought to be found, according to Faraday, in terms of the strain of the constituent molecules: (1) How can the transverse alignment of diamagnetic substances be explained? (2) What kind of polarity should diamagnetics have? (3) How can the magnetic properties of gases and space be fitted within the framework of the theory of molecular strain?

At first, Faraday felt that the transverse alignment of diamagnetics involved no theoretical difficulties. Diamagnetics can transmit the magnetic force only weakly; if they are placed in media which can take up a greater degree of strain, the effect would be to align the diamagnetic transversely to the magnetic lines of force and also to push it out of the field as the more highly magnetic medium displaced it. Diamagnetics, then, were not really different from magnetic bodies; they were only weaker. This being so, they should have the same *kind* of polarity as magnetics but of a much feebler strength. When tests for polarity were made, however, another unforeseen result was found. Diamagnetics had *no* polarity. If finely divided bismuth were sprinkled upon a sheet of paper under which a magnet was placed, the only effect was the repulsion of the bismuth particles from the magnetic pole; there was no mutual effect of the bismuth particles upon one another. Nor with other tests could any polarity be detected.

Another difficulty was encountered when empty space was the medium. Iron pointed axially and bismuth pointed transversally in a vacuum. Boscovichean point-atoms, let it be noted, were infinite in extent since the force of attraction extended to infinity, so that the alignment of the iron might still be reduced to the strain of 'contiguous' particles. But the differential action required for the transversal alignment of a diamagnetic could not be accounted for, since it involved an increase in longitudinal forces as these forces were diluted by distance—a clear contradiction.

Finally, the behaviour of gases was irreconcilable with the molecular hypothesis. Oxygen is magnetic; according to the theory of molecular strain, the oxygen molecules ought to be deformed and strained along the lines of force and the volume should decrease. Similarly, the molecules of a diamagnetic gas should be repelled by the field with a consequent expansion of volume. Using extremely sensitive gauges, Faraday sought to find these effects and failed.

For seven years he came back again and again to these problems, trying somehow to preserve the conjecture which had served him so well. Those who insist that Faraday was a strict experimentalist who, at best, devised *ad hoc* hypotheses to aid him in specific researches and quickly discarded them once the results were forthcoming, should read his laboratory journal for these years to see the hold that theory had over him.

Gradually, however, he recognized that the facts could not be forced into his hypothesis, and he quietly abandoned it as it applied to magnetism and diamagnetism. In 1852, he published a remarkable paper in the *Philosophical Magazine* entitled "On the Physical Character of the Lines of Magnetic Force". The development of the ideas contained therein may be traced back to his discovery of diamagnetism, but they are here presented in all their fullness. For many years he had spoken of lines of force, and, at least in his own mind, had meant the lines of molecular strain. We have, indeed, followed this idea from electrochemistry through electrostatic induction to the discovery of diamagnetism. By 1852, however, the physical basis of the strain had been eliminated. What Faraday would not eliminate, could not eliminate, because it presented itself so obviously to his eyes and understanding, were the lines of force themselves. That they existed independently of their means of detection—for example, iron filings or a wire cutting them to generate a current—he felt must be admitted; that the action was not simply at a distance was indicated by their curved form. But he recognized the lack of a material carrier of the force. "I cannot conceive curved lines of force without the conditions of a physical existence in that intermediate space. If they exist, it is not by a succession of particles, as in the case of static electric induction, but by the condition of space free from such material particles".

What a strange thing we now have—a strain with nothing to be strained. But wait, there is always that Aladdin's genie of the nineteenth century—the ether—to be brought in to solve all difficulties. Will not all difficulties disappear if space be filled by a subtle ethereal fluid capable of being strained by electric, magnetic and gravitational forces ? Faraday does say that a line of force "may be a vibration of the hypothetical aether, or a state of tension of that aether equivalent to either a dynamic or a static conduction". But he also goes on to point out that "it may be some other state" difficult to conceive. It may be that Faraday simply suspended his judgment over the physical basis of the strain. I cannot prove that he did not, but there is some very tenuous evidence to suggest that he saw these lines in a quite definite manner.

In January 1855, John Tyndall noted in his diary "Heard Faraday lecture. . . . Some strange views of force—I think he deceives himself by attributing an objective existence to his mental images".

Let us go back to the boy with his head stuck through the iron railings of a fence and asking on which side reality lay. Let us see the man accepting Berkeley and Boscovich and who would freely (after exhaustive empirical investigation) accept the 'objective existence' of his mental images. What would he have replied had he been asked, "What is strained in the lines of force if they can exist in space ?" I think he would have said, "Space itself". Nor should this really come as a surprise. What, after all, are the Boscovichean atoms but forces (that is, strains of some kind) in space. Or, to put it another way, to ask for a physical sub-stratum to be strained is equivalent to the demand of a material sub-stratum of force. Faraday had rejected the one; I think he saw no over-riding reason for not rejecting the other.

What then was the field ? I submit Faraday saw it as a strain in space. Matter, too, was a strain in space but it differed from the magnetic, gravitational and electric field in that it was radial (or polar), while the field was linear. The interaction of these two basic strains provided the fundamental and universal laws of the universe.

I cannot end without attempting to explain why Faraday did not come out bluntly and say that the field was a strain in space. The reason is, I feel, very simple ; he knew people would think him either mad or senile (as Tyndall hints). The incredulity which greeted Einstein's statement of much the same thing, some fifty years later, after the existence of the ether had been conclusively disproved, can serve as a rough measure of what Faraday would have faced. What Faraday left were the hints from which modern field theory has been constructed. To his contemporaries, the hints were the vapourings of an extraordinary mind which seemed to get lost in areas beyond the competence of a strict empiricist. It was more comforting to entomb him in a myth, than to follow his ideas to their revolutionary conclusion —modern field theory.

THE R. W. PAUL INSTRUMENT FUND

A REPORT ON ITS ACTIVITIES

UNDER the will of Mr. R. W. Paul, who died in 1943, a Committee was set up to administer the R. W. Paul Instrument Fund and to receive applications from British subjects who are research workers in Great Britain for grants for the design, construction and maintenance of novel, unusual or much improved types of physical instruments and apparatus for investigations in pure or applied physical science. Since its inception the Committee has voted nearly £165,000 in respect of some forty-two instruments. An account of some of these was published in 1954 (ref. 1) ; a survey of further instruments constructed or being devised is given below.

While any new instrument frequently has additional uses to the one primarily intended, it may be convenient for reading to group the instruments according to their main purposes. The absence of a particular field of physical instrument design from the following account does not mean that it would not be eligible for support from the Paul Fund. On the contrary, its absence from this account probably means that there has been no relevant application hitherto, and that such an application would have a good chance of support.

Astronomy. Astronomical interests have been the subjects of grants made to Dr. B. V. Bowden, Prof. S. Devons and Prof. R. O. Redman.

The grant to Dr. Bowden at the Manchester College of Science and Technology was originally made to the late Dr. A. Burawoy; it is being used to develop Dr. Burawoy's ideas for large optical filters with sharp transmission characteristics. These filters depend on the employment of organic compounds with better characteristics than dyes previously used, and are intended for use with telescopes of high light-gathering power.

The grant to Prof. Devons at the University of Manchester has enabled an investigation to be made into the design of a meniscus Schmidt camera for photographing emission nebulæ in *Hα* light in conjunction with narrow-band filters. The fact that the camera is designed for light of a specific wave-length enables the relative aperture to be made as high as *f*/0·7. It is hoped to publish the design details.

Prof. Redman is investigating the possibility of using comparatively thin flexible mirrors for astronomical telescopes. This would have the advantage of reducing many mechanical problems in telescope construction, since the weight of the structure could be substantially less than that of conventional telescopes. Moreover, the smaller mass of the mirror would enable it to attain thermal equilibrium more quickly. It is proposed to support the mirror by air cushions to maintain its figure as the telescope is rotated. The experimental mirror will be of 36-in. aperture, and approximately 1-in. thickness; the present investigation is concerned with finding a way of polishing and figuring such a mirror, and of designing the appropriate air supports. Another project in the University Observatories at Cambridge has been the development of multichannel spectroscopy using a Michelson-type interferometer. This development, which was initiated by Dr. P. B. Fellgett[2], has since been extended by many other workers, and is an important addition to spectroscopic techniques for use with weak sources such as occur in astronomy and in far infra-red investigations.

Nuclear and atomic physics. In nuclear and atomic physics, grants have been made to Prof. B. Bleaney and Dr. H. G. Kuhn, Dr. J. Moffatt, Mr. R. M. Sillitto and Prof. D. Gabor.

The first of these grants has facilitated the construction by Dr. G. K. Woodgate of an atomic beam magnetic-resonance apparatus[3] which has been used to measure the hyperfine structure of the ground-state of radioactive silver, ${}^{111}_{47}\mathrm{Ag}$. More recently, the apparatus has been used to develop a new method for measuring nuclear magnetic moments directly[4], and by this method it has become possible for the first time to measure the magnetic moment of a rare-earth nucleus. Such experiments have been done on the stable isotopes of europium.

The grant to Dr. Moffatt, originally made to Dr. R. Wilson, who is now in America, has been used to construct a Čerenkov radiation detector for 100-MeV. gamma-rays. A crystal of thallous chloride, 12 cm. long and 9·5 cm. in diameter, grown by the U.S. Army Engineer Laboratories at Fort Belvoir, has been used as the Čerenkov medium. The resolution (approximately 30 per cent) does not compare with that of a pair spectrometer, but the very high efficiency of detection is useful for investigating high-energy photon scattering.

Mr. R. M. Sillitto has constructed a 30-channel pulse-height analyser using transistors and cold-cathode 'Dekatron' counting tubes, and Prof. Gabor has built a new type of Wilson chamber. This uses a resonant cavity in which an electric field, very near the breakdown strength of the gas filling, is produced by a powerful 10-cm. microwave generator during the sensitive phase of the chamber. The microwave field produces an excess of tertiary electrons at its peaks, twice per cycle, and if the gas is one with high electron attachment, these tertiary electrons will turn into ion pairs inside a half-cycle, and produce periodic thickening of the tracks. This principle enables time-marks to be applied to the particle tracks at intervals of $1 \cdot 67 \times 10^{-10}$ sec., and this promises to give direct measurement of the velocity of particles in the Wilson chamber and thence their masses.

Spectroscopic analysis. Grants have been made for spectroscopic purposes to Sir Charles Dodds, Dr. P. M. B. Walker and Prof. R. V. Jones and Dr. A. H. Holbourn.

With the first of these grants a new flame spectrophotometer has been designed and constructed by Mr. R. L. Warren at the Courtauld Institute of Biochemistry, London. It is to be used for estimating trace metals in biological material. As an example of the high sensitivity achieved, less than 4×10^{-9} gm. of strontium can be determined. Details will be published shortly[5].

Dr. Walker, at the University of Edinburgh, is developing a high-speed integrating microspectrophotometer to facilitate the analysis of biological cells or liquid droplets of the order of $10^{3}\mu^{3}$ volume. One of the problems in these applications is that the distribution of the material in the specimen is non-uniform; moreover, in the biological application it is also often necessary to exclude from the measurement unwanted structures lying within the field of integration. This instrument is therefore designed to integrate the absorption of a specimen which can be resolved by the microscope, and at the same time to allow the limits of the integrated area to be accurately and quickly defined by the operator before measurement begins.

Dr. A. H. Holbourn, at the University of Aberdeen, is constructing a ruling engine for 8 cm. × 5 cm. diffraction gratings. The spacing of the lines in the grating is controlled by connecting the grating blank to the movable mirror of a Michelson interferometer. In the short lengths of gratings so far ruled there are no periodic errors, and random errors in line position are less than 2×10^{-6} cm.

Image devices. One of the most interesting developments in observational techniques has been the production of various types of image devices. In this connexion, grants have been made to Prof. G. F. J. Garlick, Dr. H. H. Hopkins, Prof. J. D. McGee and Dr. C. N. Smyth.

Prof. Garlick and Mr. M. Springford, in the University of Hull, are investigating physical problems in the design of solid-state image intensifiers. The important limiting factors have been found to lie in the photoconductor component of the device. Attempts are being made to produce cadmium sulphide and selenide layers of good sensitivity (especially to X-rays) and with more rapid response than existing materials. Stacked single crystals have been successfully used in combination with electroluminescent layers, but a more easily manufactured form of photoconductor is still being sought.

Dr. Hopkins, at the Imperial College of Science and Technology, London, has designed a static scanning fibroscope for transporting optical images without using lenses. The element of the system is a composite glass fibre, the core having a high refractive index and the sheath a low one. The fibres are assembled into flexible bundles, and light falling on the end of any one fibre is transmitted to the other end of the bundle. Since the relative positions of the individual fibres are made the same at both ends of the bundle, an image incident on one end is reproduced at the other. If flexibility is not required, the bundles can be fused together, giving a matrix of low index glass traversed by the high index fibres. In this form the device can be used as an exit window for an image intensifier, the phosphor being on the inner side of the window, and a photographic plate being in contact with the outer surface. In principle, this technique can be used to give a very large angle of collection of light without the use of lenses. Flexible bundles can be used for medical and industrial endoscopy.

Prof. J. D. McGee, also at the Imperial College, is investigating the problem of an image intensifier for X-rays. After examining the use of a television-type tube in which the photoconductive target is replaced by one highly sensitive to X-rays, Prof. McGee decided that a better approach would be to develop a high-gain image intensifier capable of detecting single photo-electrons. This image intensifier is then used to intensify the light coming from a conventional X-ray fluorescent screen. The primary limit on the quality of pictures would then be set by the fluctuations in the X-ray quanta absorbed by the screen. Development of several types of image intensifier was carried on by Prof. McGee's group, and one of these, developed by Dr. Wilcock, Mr. Emberson and Mr. Weekley, has recently approached the high performance required.

Another form of image device is the ultrasonic image camera, of which a prototype has been built by Dr. Smyth. The instrument enables a picture of internal flaws and structural details in a body to be presented on a cathode-ray screen. The body is irradiated with ultrasonic waves, and the energy scattered by inhomogeneities is focused by a plastic lens on to a quartz plate which constitutes the end surface of an electronic image tube. The piezo-electric charge pattern produced by the ultrasonic image is scanned by the electron beam in the tube, and a signal derived from the beam is made to give a visible image by normal television techniques. The prototype image has a field of 2 sq. cm. with 1,000-point resolution, and work is now proceeding to increase both the size and quality of the picture. The instrument could have applications in the inspection of materials and of objects such as the human body.

Microwaves. Although the development of microwave techniques has been very rapid during the past twenty years, there remain substantial problems in connexion with power measurement at microwave frequencies, and in the generation of waves of still shorter wave-lengths. In the former connexion, grants have been made to Prof. H. M. Barlow, at University College, London, and Prof. A. L. Cullen, at Sheffield.

Four instruments have been developed at University College, depending for their action on mechanical forces produced by the electromagnetic field and for their calibration in length, mass and time only. These instruments provide reliable standards for microwave power measurements over a wide range of values both in the 3-cm. and 8-mm. wave-bands. The 8-mm. wattmeter employs a resonant cavity, and appears to be the first instrument capable of absolute power measurements in the millimetre wave-band. A fifth instrument depends for its operation on the Hall effect produced in a small piece of semiconductor situated in an electromagnetic field. A satisfactory instrument has been developed in the 7·5-cm. and 3-cm. wave-bands for powers of the order of a few hundred milliwatts[4].

Prof. Cullen's work with Mr. M. J. de Belm at Sheffield is an extension of the work[5] which Prof. Cullen was doing under the Paul Instrument Fund grant at University College, and is concerned with the detection of microwave power at the level of microwatts or less. The measuring technique uses the fact that electromechanical forces such as radiation pressure and electrostriction depend on the square of the amplitude, so that if two separate microwave sources are used, of frequencies f_1 and f_2, the resultant mechanical force will contain a term fluctuating at the frequency f_1-f_2. It is proposed to use a quartz vibrator, resonant at this difference frequency as the sensitive element; piezo-electric voltage developed by the crystal will provide the output of the instrument.

Dating techniques. The development of physical dating techniques has been supported by grants to Dr. S. C. Curran and to Dr. E. T. Hall.

Dr. Curran, of the Royal College of Science and Technology, Glasgow, had as his objective the development of a very sensitive proportional counter of large dimensions, giving special attention to the reduction of background-rate. This incorporates shielding proportional counters, and the large inner detector is effectively wall-less. In this way the disturbance due to penetrating radiation interacting with the walls is reduced to almost negligible values. A background-rate as low as 0·4 count per min. per litre of effective volumes has been achieved, and of this more than half is due to the unavoidable interaction of penetrating radiation with the gas filling. The electronic equipment rejects all extraneous pulses with 100 per cent certainty. The system has been shown to be suitable for the examination of very ancient specimens[6], and at the same time it has been established that it will have application to other investigations such as the measurement of L/K-capture ratios[7].

The work supported by the Paul Fund and being done by Dr. E. T. Hall at Oxford is concerned with the remanent magnetism in baked clay, which can be used to obtain geophysical information about the Earth's magnetic field in archæological times and also conversely to date archæological samples of unknown age. A spinning magnetometer suitable for use with large samples (up to 18 in. in dimension) has been constructed; the speed of rotation is limited to 300 r.p.m. to avoid risk of damage to valuable specimens, and the first application of the instrument has been to the Chinese Yüeh vases. These were baked in an upright position and consequently retain the contemporary angle of dip. In the same laboratory the construction of a fully automatic gamma-ray spectrometer, employing electronic Compton spectrum subtraction, has permitted large-scale programmes of neutron activation analyses of early Greek silver coins and Roman pottery[10]. Because the technique is entirely non-destructive, it has been possible to analyse some 500 coins, probably more than the sum total of all archæological coin analyses done by other methods.

Information about application for grants from the R. W. Paul Instrument Fund can be obtained from the Assistant Secretary, Royal Society, Burlington House, Piccadilly, London, W.1.

CONTENT OF CÆSIUM-137 AND (ZIRCONIUM + NIOBIUM)-95 IN SWEDISH SOILS

By KERSTIN LÖW and K. EDVARSON

Research Institute of National Defence, Department 4, Stockholm, 80

FOR determining the accumulated fall-out deposit on the ground, γ-spectrometric determination of fission products in the surface layers of soil seems to have distinct advantages compared with other methods[1-3]. Evaluation of the deposit from measurements of activity in precipitation has a disadvantage in that the sampling efficiency of the collecting device differs from that of the ground, and further makes it necessary to add up contributions from a number of samples, which, in the case of long-lived components, will become very large. Radiochemical determinations of the fission-products in soil are rather time-consuming and involve difficulties as regards determination of the chemical yields. γ-spectrometric determination of a nuclide in soil is possible if it has a γ-line well resolved from other γ-lines and with an intensity comparable to the natural γ-activity of the soil. In this article, measurements on soils sampled in June 1959 are reported. In this case it was possible to determine cæsium-137 and zirconium + niobium-95.

The samples were taken on June 10–12, 1959, on pasture-ground not cultivated during the past five years at two latitudes across the country, 60° N. and 63° N. respectively (Fig. 1). As it was of interest to correlate the deposit with the amount of precipitation, the samples were collected in the immediate vicinity of weather stations. At each site three cores with an area of 320 cm.^{2} and a depth of 10 cm. were taken at a distance of a few metres. The cores were cut in four layers with a thickness of 2·5 cm. each. The vegetation was included in the top layer. After drying at 110° C. the corresponding layers from the three cores were thoroughly mixed. Due to the different soil characteristics, the volume of these bulk samples varied between 1·5 and 3 litres. The γ-spectrometric determinations were made with the apparatus already described[2] (10 cm. × 10 cm. sodium (thallium) iodide-detector and 70-channel

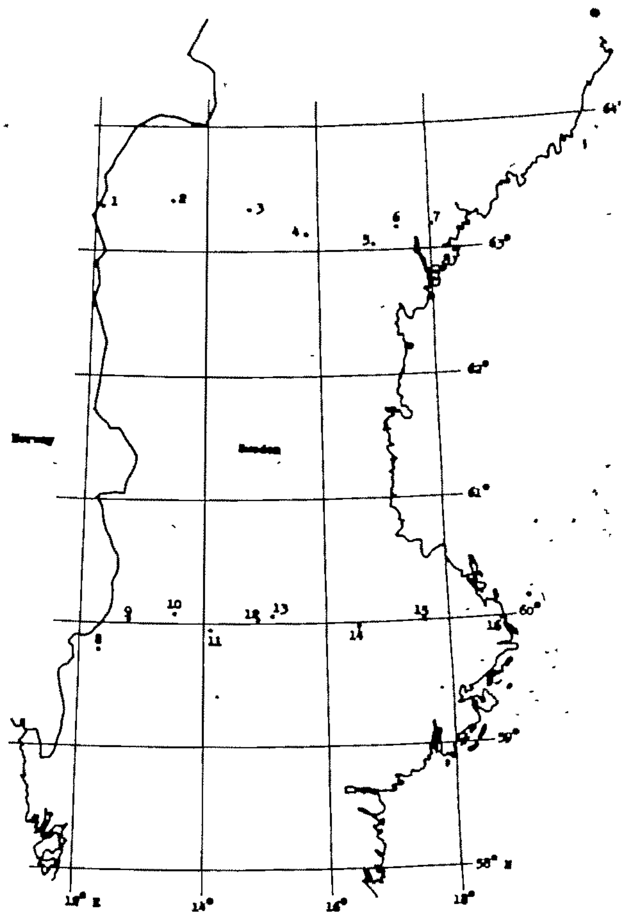

Fig. 1

kicksorter). The sample container had a volume of 1·0 litre and the measured samples thus corresponded to an area of 350–700 cm.^{2}. In five cases a duplicate determination on different parts of the bulk samples was made. The bottom layer was assumed to contain no fission product γ-activity, and its spectrum was used for the subtraction of the natural activity contribution in the spectra of the two upper layers in the manner already described[3]. As it was found that the fission-product activity in the 2·5–5 cm. layer was much lower than in the top layer, it was not considered necessary to measure the 5–7·5 cm. layer.

The results are summarized in Table 1. When recalculating the zirconium + niobium-95 values to the sampling date, a half-life of 65 days has been used, as the latest probable origin of the activity is the tests in the autumn 1958 and thus a transient equilibrium between zirconium and niobium-95 can be assumed. A determination of a sample from Bergen, Norway, taken in November 1959, is also included. (This sample was kindly provided by Mr. T. Hvinden at the Norwegian Defence Research Establishment.)

The random errors in the measurements are estimated as 3 per cent for zirconium + niobium-95 and 7 per cent for caesium-137 in the top layers. For the 2·5–5 cm. layers, the absolute random errors are of the same order of magnitude, thus giving a total random error in the determination of the deposition on each location of 5 per cent for zirconium + niobium-95 and 10 per cent for caesium-137. There might further be an error due to incomplete mixing of the bulk samples. The differences found between duplicate samples indicate that this error is considerably less than 10 per cent. Apart from the random errors there is a constant systematic calibration error of < 10 per cent.

As the half-life of caesium-137 is long, compared with the period of fall-out from nuclear explosions, the deposit of this nuclide represents the accumulated fall-out since the beginning of nuclear weapon tests. The deposit of zirconium + niobium-95 (half-life 65 days) will mainly originate from recent tests. In the present case it could be assumed[4] that almost all the zirconium + niobium-95 deposit originated from the tests carried out in the autumn of 1958.

If it is assumed that the fall-out is a function of the precipitation, it will thus be of interest to correlate the caesium-137 deposit with the total precipitation

15	16.9	15·0, 14·3 1·2	16	105, 94 0	100	2,270	284
16	19.9	19·7 3·3	23	88 9	97	2,550	344
Bergen	8.12	76, 87, 87 8, 9, 9	92	581, 601, 574 74, 54, 54	646	9,100	—

In columns 3 and 4 the upper value is the activity in the 0–2·5 cm. layer, the lower the activity in the 2·5–5 cm. layer. The sum is given to the right. The samples 1–16 were taken during June 10–12, 1959, the sample from Bergen in November 1959.

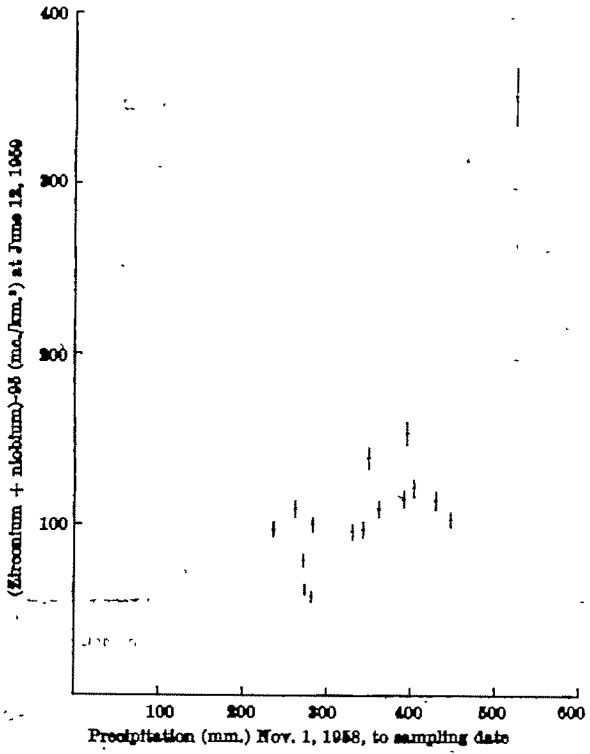

Fig. 3

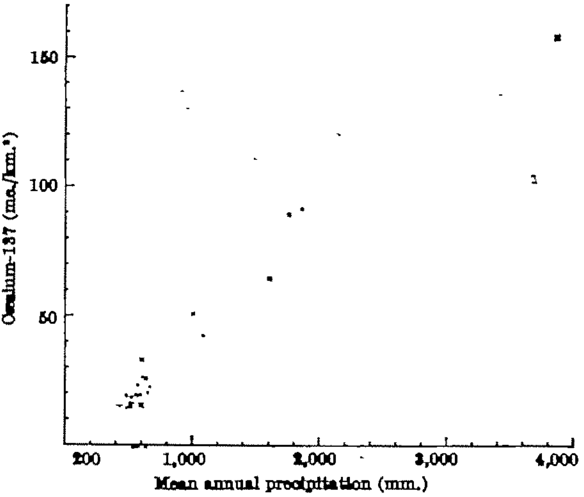

Fig. 4

since the beginning of considerable global fall-out, and the zirconium + niobium-95 deposit with the precipitation since the autumn, 1958.

As can be seen in Figs. 2 and 3, a strong linear relationship seems to exist between caesium-137 deposit and precipitation (ρ = 0·99 with the 95 per cent confidence limit 0·95 and 1·00), whereas the zirconium + niobium-95 values are more scattered (ρ = 0·74 with the 95 per cent confidence limits 0·35 and 0·90). In the case of zirconium + niobium-95, the value for Bergen has not been included because of the later sampling date.

The larger irregularities in the zirconium + niobium-95 values are not unexpected. Large variations in the specific activity of precipitation have been observed between samples taken simultaneously at different locations[4], and such variations will be reflected in Fig. 2. Corresponding variations in the case of caesium-137 will be levelled out because of the long period of accumulation. Of course it is also quite possible that the variations in the specific caesium-137 activity in precipitation are smaller.

If the values for Bergen and station 1 are excluded the mean value of the caesium-137 deposit is 18·7 mc./km.² and the standard deviation is 3·5 mc./km.². The corresponding precipitation values vary within ± 20 per cent. This precipitation interval applies to the greater part of Sweden, and the above value can thus be regarded as a reasonable mean value for the country.

Peirson has recently published a corresponding study concerning the deposit in the United Kingdom on samples taken during the summer, 1959[3]. In Fig. 4, Peirson's and our values of the caesium-137 deposit are plotted against the mean annual precipitation. No significant differences between the two sets of values can be detected. As the latitude of the British sampling sites is 50–55° N., while the Swedish sites are at 60–63° N., this concordance is of interest.

For the selection of sampling sites and for carrying out the sampling we are indebted to Dr. L. Fredriksson at the Royal Agricultural College, Ultuna.

OBITUARY

Prof. Max von Laue, For.Mem.R.S.

Prof. Max von Laue, former director of the Fritz-Haber-Institut of the Max Planck Gesellschaft in Berlin Dahlem, died in Berlin on April 24 a few months after his eightieth birthday.

In an autobiographical note, Max von Laue once described the early influence upon him of his excellent science teacher at the *Gymnasium* in Strassburg, and also his great interest in H. v. Helmholtz's popular lectures. These were the determining factors which made him choose physics and mathematics, and in 1898 he began to read physics at the University of Strassburg—probably against the will of his father and step-mother, who would have liked him to become an officer in the Prussian Army. In 1899 he moved to Göttingen, where he came under the spell of David Hilbert, whom he regarded as probably the greatest genius he ever met in his life. However, it was Waldemar Voigt who taught him to apply mathematical methods to physics. v. Laue became a theoretical physicist, and, after a short interlude in

Munich—short, because Boltzmann's chair was still vacant and there was no one to teach theoretical physics—he went to Berlin. It is likely that during these years, 1902–4, the fundamentals were laid for the discovery which, ten years later, brought Laue world fame and a Nobel Prize in Physics. It was indeed one of the greatest discoveries of the century. He attended Max Planck's lectures on theoretical optics and Lummer's on special problems of optics. Laue remarked that during these formative years he acquired his 'optical instinct' which stood him in such good stead later. The subject given to him by Planck for his dissertation was "Theory of Interference on Plane Parallel Plates".

Laue became the devoted pupil of Planck, and Berlin his spiritual home. After two more years postgraduate work in Göttingen, he returned in 1905 to Berlin as lecturer and as Planck's assistant. It was Einstein's *annus mirabilis*. Laue's early work on relativity—with his many contributions to thermodynamics, the theory of radiation and also his phenomenological theory of superconductivity—seem, to-day, unjustly eclipsed by his X-ray diffraction work. It led to his monograph on the special theory of relativity (1910)—the first ever written—and later to another on the general theory of relativity.

In 1909, v. Laue moved to Munich, and it was there, in 1912, that he made one of the greatest and most far-reaching discoveries of our own age, the diffraction of X-rays by crystals. The scientific atmosphere in Munich at this time was especially favourable for this discovery. W. C. Röntgen was still active, and A. Sommerfeld, a firm believer in the wave nature of X-rays, had succeeded Boltzmann. Sommerfeld's influence in theoretical physics through his own research and by his teaching was probably greater than that of anyone else. Also in Munich was Paul von Groth, the mineralogist, continuing the tradition of Leonhard Sohncke, who in his time had contributed greatly to the theory of crystals. There was, too, young P. P. Ewald seeking advice on wave optics, whose work suggested to v. Laue the idea of the experiment performed by W. Friedrich and P. Knipping. The second experiment, using copper sulphate as crystal, showed the result which v. Laue predicted. Many research workers before this had sent X-rays through crystals, limiting their observations to the direct beam, without noticing anything of interest. It was left to v. Laue's genius to expect, and find, diffracted rays on the photographic plate. The theory of one- and two-dimensional gratings, so well known to v. Laue, was easily extended to a three-dimensional grating such as he proved to exist in the regular arrangement of atoms in crystals. Max von Laue's discovery was made "by the sheer power of believing more concretely than anyone else in the accepted theory of crystals and X-rays. These advances were no less bold and hazardous than were the innovations of Copernicus, Planck or Einstein" (M. Polanyi).

It is impossible to describe shortly the consequences of this discovery on the development of almost every branch of science. This door, opened in 1912, is still wide open nearly fifty years later. Only recently the results have been described in *Nature* of fundamental work by Kendrew and Perutz which would not have been possible but for the historical experiment in Munich. Sir Lawrence Bragg, confining himself to X-ray analysis only, has given a masterly account of the advances in the determination of crystal structures in a volume dedicated to three octogenarians—Lise Meitner, Otto Hahn and Max von Laue. v. Laue himself was never interested in developing his discovery into a tool for crystal structure analysis; instead, he followed the course of developing the optical background of X-ray diffraction, work which is recorded in the various editions of his book, "Röntgenstrahl Interferenzen".

After a short spell as professor in Zurich and Frankfurt, von Laue returned to Berlin as professor of theoretical physics and co-director, with his life-long friend, A. Einstein, of the Kaiser-Wilhelm-Institut fur Physik. He remained in Berlin all his life, becoming, after the Second World War, director of the Fritz-Haber-Institut. Well over 200 papers, on almost every aspect of theoretical physics, and a number of books—among them a short history of physics—were the result of his work. However, in spite of his lively interest, he never contributed to the development of quantum mechanics. He shared, with his friends Planck and Einstein, certain reservations towards its final consequences.

Berlin, after the First World War and before 1933, had become one of the great centres of learning. A regular scientific event was the "Laue Colloquium" at the Physics Department in Reichstagsufer, unforgettable to anybody who had the good fortune to attend it regularly. Every week, and under the chairmanship of v. Laue, there took place a gathering of eminent men of science, of those who later became eminent, and of everybody else interested in new developments of physics. Planck, Nernst, Einstein, Schroedinger, Lise Meitner, R. Ladenburg and, later, Debye and G. Hertz all attended regularly. Among those who came to great eminence later on were F. Simon, J. von Neumann, L. Szilard, E. Wigner and F. London. It was a very democratic institution, and everybody was allowed to ask questions, intelligent and, sometimes, silly ones. All this, and the spiritual values of this period, came to an abrupt end in 1933. The material destruction which followed during the War was a direct consequence of the political events of 1933. It was during these fateful years that von Laue showed the greatness of his personality. He became a lonely and very courageous fighter for truth and integrity against tyranny and the evils of a wicked regime. He was probably the only member of the Academy who launched a solemn protest against Einstein's expulsion from the Prussian Academy of Sciences. The era of 'Aryan physics' began, and it was decreed, mainly by obscure men, but unfortunately also by two great physicists, who sprang out of oblivion, that Einstein's and other Jewish physicists' names and work must in future be ignored. Again, it was Laue, at a meeting of the German Physical Society (Würzburg, September 1933), who replied spontaneously to an address by Johannes Stark on the role and task of physics in the Third Reich. Laue reminded the audience that, almost exactly 300 years before, Galileo was forced, under threat of torture by the Inquisition, to renounce his doctrine. He passionately appealed to the physicists to bear in mind Galileo's famous words: "It moves, nevertheless!" The following year his obituary of Fritz Haber, published in *Die Naturwissenschaften*, would have had dangerous consequences for v. Laue had not the Gestapo been afraid of the reaction of the civilized world to the persecution of the man who dared to say: "Just as Themistocles has become immortal as the victor of

Salamis, and not as the conqueror of the Persian king, Fritz Haber has become immortal by his scientific work".

During the War, v. Laue became somewhat of a recluse. His only son was safe in the United States studying history. His house, where he lived with his wife and daughter, was visited by a handful of friends who thought as he did, by the sons and friends of Dutch and Norwegian scientists sent as slave workers to Germany, by French prisoners of war and many more who needed his help or advice. In 1941 he went with half a dozen friends to the derelict Jewish cemetery to pay his last respects to his old friend, Dr. Arnold Berliner, founder and, for twenty-five years, editor of *Die Naturwissenschaften*. Berliner had been forced to resign by the Nazis, and had committed suicide rather than be expelled from his home and sent to a concentration camp. Carbon copies of the obituary Laue wrote were sent to several of his friends for safe keeping, and published after the War. v. Laue never had the slightest doubt that Germany would lose the War. In 1943 he was seriously rebuked by the Nazi Minister of Education for mentioning Einstein's name in a lecture. In reply to this, he published shortly afterwards a paper, "Ein relativistischer Beweis fur das Wien'sche Verschiebungsgesetz".

When the end of the War came, v. Laue was in Hechingen, where the Institute had been evacuated. With a team of German atomic scientists, known as the 'Uran-Verein', v. Laue was sent as a 'prisoner' to England. Naturally, v. Laue was not 'trustworthy' enough to have become a member of this team, and in any event he would have refused his co-operation. Some of the letters he wrote to friends at this time about the reaction of his colleagues to Hiroshima, and their subsequent discussions on the atom bomb, are carefully preserved documents of great historical interest.

Returning to Germany, he put all his efforts into rebuilding science. In 1946 he was, with Max Planck, the first German to be invited to England. He received many honours and was elected a foreign member of the Royal Society in 1949. His ashes are buried at Göttingen cemetery beside the graves of Walther Nernst, Adolf Windaus and Max Planck—four members of a great period of science in Germany.

P. ROSBAUD

NEWS and VIEWS

Botany at Adelaide: Prof. R. N. Robertson

PROF. R. N. ROBERTSON, who is to succeed the late Prof. J. G. Wood as professor of botany in the University of Adelaide, graduated from the University of Sydney in 1934. In 1936, he went to St. John's College, Cambridge, as a Scholar of the Royal Commission for the 1851 Exhibition. After graduating with a Ph.D. degree in plant physiology, he joined the lecturing staff of the University of Sydney in 1939. In 1946 he joined the Commonwealth Scientific and Industrial Research Organization, in which he afterwards became a chief research officer and is now a member of the executive. With Prof. F. V. Mercer, he founded the Plant Physiology Unit, which is run jointly by the Department of Botany, University of Sydney, and the Organization's Division of Food Preservation and Transport. During 1958–59 Prof. Robertson was a visiting professor in the Department of Horticultural Science of the University of California at Los Angeles. His research has been concerned with problems of salt accumulation and respiration in plant cells and in plant mitochondria. In addition, he has carried out work on the developmental physiology of fruits with special reference to respiration. Because of his commitments to the Commonwealth Scientific and Industrial Research Organization's Executive, Prof. Robertson will not take up his duties in Adelaide until the beginning of 1962, and in the meantime Dr. H. B. S. Womersley has been appointed as acting-head of the Department.

International Meteorological Organization Prize: Prof. J. van Mieghem

THE Executive Committee of the World Meteorological Organization has this year awarded the annual prize paid for from the funds left to it by the International Meteorological Organization to the eminent Belgian meteorologist, Prof. J. van Mieghem. The prize consists of a gold medal, 1,200 U.S. dollars and a diploma. Prof. van Mieghem is chief of the service for theoretical and experimental aerology of the Royal Meteorological Institute of Belgium. He is also professor of meteorology in the Free University of Brussels and chairman of the Belgian National Centre for Polar Research. In its selection, the Committee takes into account both scientific eminence and the record of work done in the field of international meteorological organization. Under the first heading, Prof. van Mieghem is a mathematician of the first order, who has published about a hundred papers on the dynamics and thermodynamics of the atmosphere, with the subject of energy transformations as his major field of research. His contributions to the international organization of meteorology are also very large. He was president of the Technical Commission for Aerology of the World Meteorological Organization during 1951–57, and in the International Union of Geodesy and Geophysics he has been secretary (1948–54), vice-president (1954–57) and president (from 1957) of the International Association of Meteorology and Atmospheric Physics. Probably his major work in this sphere, however, was as chairman of the World Meteorological Organization Working Group for the International Geophysical Year and representative of the Organization on the Special Committee for the International Geophysical Year.

The Swinburne Medal of the Plastics Institute

THE first award of the Swinburne Medal of the Plastics Institute has been made to Prof. G. Gee, professor of chemistry in the University of Manchester, for his outstanding contributions to the advancement of polymer chemistry. Prof. Gee will deliver his Swinburne Address at the Royal Institution on Thursday, February 16, 1961, when he will be presented with the Gold Medal and the sum of money which accompanies the award. The award was instituted in 1959 to commemorate Sir James Swinburne, who died at the age of a hundred in the previous year; it has been generously endowed by Bakelite, Ltd.

Editorship of *Discovery*: Mr. S. E. Gamarekian

S. Edward Gamarekian has been appointed editor of *Discovery*. He carried out research and development work at the General Electric Company's Laboratories in Schenectady, New York, for many years and lectured at Rutgers University, Rensselaer Polytechnic Institute and the Georgian Institute of Technology. He later became the scientific correspondent for *The Washington Post* and recently came to Britain to report on scientific developments for *The Guardian* during a three-month exchange of science correspondents between the two newspapers.

Recovery of Capsules from *Discoverer* Satellites

The first success in retrieving an object which had returned to Earth after being in orbit in space was achieved on August 12, when the re-entry capsule from the United States satellite *Discoverer* 13 was recovered from the North Pacific. *Discoverer* 13 (1960 θ) was launched from Vandenberg Air Force Base, California, at 20h. 40m. U.T. on August 10, and entered an orbit inclined at 83° to the equator. Its height varied between 260 km. at perigee and 700 km. at apogee, the orbital period being 94·1 min. Seventeen revolutions later, the re-entry capsule was detached from the main body of the satellite when it was travelling south near the Aleutian Islands, and, after its speed had been substantially reduced by a retro-rocket, it descended through the atmosphere. In the last few miles of its descent it was further retarded by parachute and was finally recovered from the sea north of Hawaii. It was found to have withstood well the heating encountered during its descent. On August 19 there was successful recovery of a second capsule, ejected from the satellite *Discoverer* 14 (1960 κ), which was launched at 19h. 58m. U.T. on August 18 into an orbit similar to that of its predecessor. On this occasion the capsule, which weighed 85 lb., was intercepted during its final parachute descent, being caught by an aircraft at an altitude of about 10,000 ft. over the north Pacific.

The Satellite *Echo* 1 (1960 ι)

The first successful balloon-satellite was launched from Cape Canaveral in Florida at 09h. 40m. U.T. on August 12. The satellite, known as *Echo* 1, consists of an aluminium-coated plastic sphere 100 ft. in diameter, which was inflated at high altitude. Its orbit is inclined at 47° to the equator, with a period of revolution of 118·2 min. initially. The orbit is nearly circular, the height being 1,530 km. at perigee and 1,690 km. at apogee. The satellite, which is designated 1960 ι 1, is accompanied in orbit by its final-stage rocket (1960 ι 2), and three other fragments. The main purpose of the satellite is to act as a reflector for radio waves, and many transmissions have been successfully received via the satellite. It thus serves as a first step towards a world-wide communications system which would be independent of ionospheric disturbances. The satellite is also admirable for optical tracking, and during its first week in orbit was easily visible from most of the northern hemisphere, as a slow-moving object of stellar magnitude zero. The satellite should also yield the first information on air density at heights above 1,000 km., and evidence of its behaviour under the impact of meteorites is awaited with interest.

Australia's Second Atomic Reactor

Australia's second atomic reactor is to be called by the aboriginal name of *Moata*. This is the first in the world to bear a tribal name. The name *Moata* is used by the Ngerikudi tribe in Northern Queensland to describe instruments for making heat or 'native firesticks'. *Moata*, an Argonaut type of experimental reactor, is now under construction at the Advanced Technology Laboratories at Mountain View, California, and will be installed at Lucas Heights early next year.

Information Centre for Food Irradiation

An international information centre for food irradiation has been set up as a result of a contract signed between the European Productivity Agency of the Organization for European Economic Co-operation and the Centre d'Etudes Nucléaires at Saclay, France. M. Pierre Lévèque has been appointed director of the Centre, which will be set up at Saclay. The functions of the Centre include the preparation, publication and distribution of a quarterly international newsletter on food irradiation in both English and French. The Centre will also serve as a point of contact between scientists, food technologists and the government and industrial circles interested, and will encourage closer international co-operation in the development and application of knowledge in the field of food irradiation. The contract, which has been signed for an initial period of two years, provides for the payment by the sponsoring bodies of a sum of 32,000 new francs to cover printing and translation costs and other incidental expenses of the Centre. It is hoped that the work of the European Information Centre for Food Irradiation will encourage investigation and research and promote the successful industrialization of the results obtained.

Bibliographies on Technical and Vocational Education

A series of bibliographies on technical and vocational education has been launched by Unesco. Besides an international bibliography, surveys have been published giving details of publications in the United Kingdom and in the U.S.S.R. concerned with the technical and vocational aspects of education. To these is now added a bibliography of technical education publications in the United States (Educational Studies and Documents No. 36: Technical and Vocational Education in the U.S.A.—a Bibliographical Survey prepared by the United States Office of Education. Pp. 24. (Paris: Unesco; London: H.M. Stationery Office, 1959.) 3*s.* 6*d.*) The booklet is in five parts and lists separately publications dealing with general technical and vocational education, agriculture, distribution, home economics and industrial education; there is an explanatory note to cover each publication described, stating briefly its contents and purpose.

Low-priced Books for Overseas

Since this scheme was first started, some 2,000 titles have been submitted by publishers and others to the Advisory Committee on the Selection of Low-priced Books for Overseas under the chairmanship of Mr. A. L. P. Norrington, president of Trinity College, Oxford, and vice-chancellor (designate) of the University. The Committee will shortly be submitting its list of recommendations to the Ministers concerned. Some measure of priority is being given to university text-books, as the importance attached to the supply of books of educational, scientific and technical value was clearly brought out at the

Commonwealth Education Conference held in July 1959. The Advisory Committee is therefore studying a first list of some twenty-five scientific and technical text-books for issue in low-priced editions to universities and college libraries, instructors and individual students. Initially the arrangement will be applied to India. It is hoped that the books will be made available for distribution in India this winter.

The Proterozoic in the U.S.S.R.

THE rocks belonging to the Upper Pre-Cambrian or Proterozoic group in China, named by Grabau as belonging to the Sinian system, during the past two decades have been proved to be very abundant in the Urals and other parts of the U.S.S.R. In the absence of characteristic fossils which would allow a correlation with the Sinian, the prominent Soviet geologist, N. S. Shatsky, in 1945 proposed the name of Rhiphaean system, from Rhiphaean Mountains, an old name for the Ural Mountains. Recent work on the determination of the absolute age of these formations, as presented by B. M. Keller (*Priroda*, 9, 30; 1959), gives the following figures: Taratash gneiss underlying Rhiphaean series, 1,100 m.y.; uppermost Rhiphaean deposits—Inzer sandstone, 865 m.y.; Serdobian suite rocks, 680 m.y.; Larminarites suite, 540–560 m.y. Thus, the Rhiphaean system may be demarcated in age as 1,100–500 m.y. It is divided into the Upper Timanian suite and the Lower Yakutian suite. The rocks of the Yakutian suite are characterized by a peculiar calcareous alga of a stromatolite type named *Conophyton*, while in the Timanian suite a branching alga named *Collenia* is found. These two algal types form very thick layers of limestone, but no remains of animals have as yet been found in these rocks. While V. P. Maslov studied these algae, S. N. Naumova has discovered spores of land or, more probably, of shore plants, which was rather unexpected. In Siberia, especially in the region of the Lake Baikal, the Upper Rhiphaean strata are folded and intruded by granite, and so N. S. Shatsky applied the name Baikalian to the orogenetic and magmatic epoch of this age. Within the area of the present Russian platform the Baikalian tectonic movements led to the production of three major shields—Baltic, Sarmatian and Tartarian—and two major geosynclines—Scandinavian and Uralian. The geosynclinal Rhiphaean sediments were deposited in well-marked sedimentary cycles, beginning with coarse conglomerates and breccia and finishing with fine-grained sediments.

Excavations at Dzibilchaltun in Yucatan

AN account of excavations carried out during three seasons by the National Geographic Society and Tulane University at Dzibilchaltun in north-western Yucatan, Mexico, has now been published (*Proc. Amer. Phil. Soc.*, 104, No. 3; June 15, 1960). Little has been known about the early phases of culture in this part of the world, and the exploration of some large buildings and temples and the determination of a definite stratigraphy are of great interest. To the prehistorian the date of the constructions (round about A.D. 500) might seem somewhat modern, but much hitherto unknown information of the earlier cultures in those little explored areas is here unfolded.

Nature Conservancy Awards for 1960

THE Nature Conservancy announces the following awards of research studentships for postgraduate training in ecology, tenable for periods up to three years at the universities shown: *Botany:* Miss M. C. Anderson (Cambridge), P. E. Gibbs (Liverpool), Miss M. M. McGrath (University College of North Wales, Bangor), J. G. Pusey (Oxford); *Zoology:* R. A. Avery (Bristol), D. E. Baird (Oxford), P. P. G. Bateson (Cambridge), Miss V. Healey (Manchester), D. J. Hobden (Southampton), W. W. Murdock (Oxford), Miss M. A. Murphy (Manchester), D. C. Seel (Oxford), J. B. Whittaker (Durham); *Geography:* Miss J. Wain (London); *Diploma Course in Conservation and Ecology at University College, London:* G. P. Allen, J. M. Davidson, K. East, A. J. Kerr, Miss J. J. Rowe, D. A. White.

The Beilby Medal and Prize, 1961

SINCE 1930, at intervals of one or more years, awards have been made by the administrators of the Sir George Beilby Memorial Fund, representing the Royal Institute of Chemistry, the Society of Chemical Industry and the Institute of Metals. In 1958 two awards, each of 150 guineas, were made. It was then agreed that no further award would be made before 1960. The administrators have now decided that henceforth each award shall consist of a gold medal as well as a substantial sum of money, and shall be known as "The Beilby Medal and Prize" and specified as being "For Advancement in Science and Practice". Such an award will be offered at intervals of two years, but more than one may be made on the same occasion if there are several candidates of sufficiently outstanding merit. Consideration will be given in due course to the making of an award (or awards) from the Fund in 1961, for outstanding work on the development and application of scientific principles in any field related to the special interests of Sir George Beilby, namely, in chemical engineering, fuel technology or metallurgy. Applications must be submitted not later than December 31, 1960, by letter addressed to the Convenor of the Administrators, Sir George Beilby Memorial Fund, Royal Institute of Chemistry, 30 Russell Square, London, W.C.1.

The Scientific Instrument Manufacturers' Association

THE following have been elected officers and council of the Scientific Instrument Manufacturers' Association of Great Britain for the year 1960–61: *President*, Mr. G. C. Ottway (W. Ottway and Co., Ltd.); *Vice-Presidents*, Mr. A. W. Jones (Fleming Radio (Developments), Ltd.), and Mr. L. A. Woodhead (Conor Instruments, Ltd., and retiring president). *Honorary Treasurer*, Mr. A. W. A. Rundle (A. Gallenkamp and Co., Ltd.); *Honorary Secretary*, Mr. E. R. Ponsford (Solartron Electronic Group, Ltd.); *Council Members*, Mr. S. T. Pickering (Chance Pilkington Optical Works), Mr. G. M. Sisson (Sir Howard Grubb Parsons and Co., Ltd.), Mr. G. S. Sturrock (Kelvin and Hughes, Ltd.) and Mr. R. Foxwell (The Wayne Kerr Laboratories, Ltd.).

University News: Churchill College, Cambridge

MR. C. ST. J. WILSON, of Corpus Christi College, has been elected to a fellowship as from October 1. The following elections to junior research fellowships from October 1 are announced: R. A. Y. Jones, of Clare College; A. O. Gilchrist, of Trinity Hall (Sydney Harvey Fellowship); C. B. Cottrell, University of the Witwatersrand and Queens' College

(Gulbenkian Fellowship); A. Howie, University of Edinburgh and Trinity College.

The following have been elected to Overseas Fellowships: Prof. E. E. Saltpeter, of Cornell University (from April 1, 1961); Dr. J. D. Watson, of Harvard University (from October 1, 1961).

Leicester

The following appointments have been made: Dr. S. G. M. Lee (Bedford College, London), to the new chair of psychology; Dr. M. C. R. Symons (Southampton), to the new chair of physical chemistry; Dr. H. L. Kornberg (Oxford), to the new chair of biochemistry.

Senior lecturers have been appointed as follows: W. B. Birmingham (economics); Dr. J. E. Brown (engineering); Dr. O. P. D. Cutteridge and Dr. R. W. Maxwell (engineering). Lecturers appointed include P. S. Cohen (sociology), D. J. Cockrell (engineering), and Dr. W. Sluckin (psychology).

London

Dr. Richard Creese, senior lecturer in physiology at the London Hospital Medical College, has been appointed to the readership in physiology tenable at St. Mary's Hospital Medical School.

Dr. L. M. Jackman, lecturer in organic chemistry in the Imperial College of Science and Technology, has been appointed to the University readership in organic chemistry tenable at that College.

Nottingham

Prof. A. G. Smith, professor of aircraft propulsion at the College of Aeronautics, Cranfield (see *Nature*, 181, 528; 1958), has been elected the first holder of the Hives chair of thermodynamics, endowed by Rolls-Royce, Ltd., in the University of Nottingham. Prof. Smith will be the head of the Department of Mechanical Engineering in succession to Prof. J. A. Pope.

Southampton

Westland Aircraft Ltd. has made a contribution of £17,500 to the centenary appeal issued by the University to provide, over a seven-year period, for a readership in helicopter engineering. The University has also gratefully accepted the offer by Union Carbide Ltd. of £2,150 per annum, for three years in the first place, to provide for a research fellowship and a research studentship in the Department of Chemistry.

Announcements

The Minister for Science, Lord Hailsham, has re-appointed the following part-time members of the United Kingdom Atomic Energy Authority: Lord Citrine, from January 1, 1961, when his present term of office expires, to December 31, 1961; Sir James Chadwick, from August 21, 1960, to August 20, 1962; Mr. C. F. Kearton, from October 17, 1960, to October 16, 1965.

Mr. James C. Bradley has been appointed as assistant secretary (management) of the Smithsonian Institution. Mr. Bradley succeeds Dr. John L. Keddy, who retired recently. Since January 1959, Mr. Bradley has served as assistant to the secretary, Dr. Leonard Carmichael, in the administration of the Institution's scientific, technological and cultural programme.

Dr. Marcel Autret, known for his work in the field of kwashiorkor and other protein-deficiency diseases, has been appointed director of the Nutrition Division of the Food and Agriculture Organization, in succession to Dr. W. R. Aykroyd. Dr. Autret joined the Organization in 1949, after a career in the French Colonial Service; he first became interested in nutrition while stationed in French Indo-China as head of the Chemistry Department of the Pasteur Institute in Saigon.

Miss Jennifer Remfry (Bedford College) has been appointed Junior Universities Federation for Animal Welfare (UFAW) Research Fellow to assist Dr. Phyllis G. Croft, UFAW Research Fellow, at the Royal Veterinary College, in research relating to anæsthetics and relaxants.

The next award of the Meldola Medal, the gift of the Society of Maccabaeans, will be made early in 1961 to the chemist who, being a British subject and less than thirty years of age on December 31, 1960, shows the most promise as indicated by his or her published chemical work. Further information can be obtained from the President, Royal Institute of Chemistry, 30 Russell Square, London, W.C.1, the envelope being marked 'Meldola Medal'.

For the sole use and convenience of its members the Physical Society of Japan has from time to time issued in a single volume a series of selected papers reprinted, with permission of the various publishers, from different American and European journals and dealing with a specific field of research. The latest in the series contains sixteen papers on the theory of atomic nuclei and includes articles, by N. Bohr, J. Frenkel, W. Heisenberg, L. Landau, E. Teller, V. F. Weisskopf and J. Wheeler. The period covered is 1932–40.

A course of lectures on "Problems of Radioactivity at Water and Sewage Works" will be held in the Manchester College of Science and Technology during September 29 and 30. Applications to attend must be sent to the Registrar of the College not later than September 19.

The Second Accelerator Conference is being organized by the High Voltage Engineering Corporation and its Dutch subsidiary and will be held in Amsterdam during October 4–6. It is hoped to cover most aspects of low-energy accelerator techniques in physics and in industry. Further information can be obtained from High Voltage Engineering (Europa) N.V., Post Box 99, Amsterdamseweg 57, Amersfoort, The Netherlands.

A symposium of five papers on "Drugs for the Treatment of Hypertension", arranged by the Royal Institute of Chemistry (Manchester and District Section) and the Society of Chemical Industry (Manchester Section and Fine Chemicals Group), will be held in the Tenants Hall, I.C.I. (Pharmaceuticals Division), Alderley Park, near Macclesfield, Cheshire, on September 30. After the symposium there will be a tour of the Research Department of I.C.I. (Pharmaceuticals Division). Further information can be obtained from Dr. G. A. Gamlen, Research Department, I.C.I. Ltd., Dyestuffs Division, Hexagon House, Blackley, Manchester 9.

Erratum. Dr. T. E. Cleghorn points out that a printing mistake occurred in the title of his communication in *Nature*, 184, 1324 (1959); this should read "A 'New' Human Blood Group Antigen, Sw^a".

SPACE RESEARCH IN BRITAIN: GRANTS

SIXTEEN grants to British universities for space research projects, totalling £184,540, have been made on the recommendation of the British National Committee on Space Research, set up by the Royal Society under the chairmanship of Sir Harrie Massey. The grants, which cover a variety of periods, are for salaries of staff, travel and subsistence, and development or purchase of special equipment. These grants have been approved by the Steering Group for Space Research, set up by the Minister for Science under the chairmanship of Sir Edward Bullard, and the financial responsibility for them is with the Department of Scientific and Industrial Research:

University College of Wales, Aberystwyth, £16,530 over 3 years, to Prof. W. J. G. Beynon for measurement of electron density/height profiles with rockets using the Doppler method and the pulse method.

Queen's University, Belfast, £15,005 over 2 years, to Prof. D. R. Bates for upper atmospheric rocket research, including artificial air-glow, altitudes of night-glow layers, and a study of micrometeorites.

University of Birmingham, £26,000 over 3 years, to Prof. J. Sayers for electron and ion-population studies of the upper atmosphere and interplanetary space.

University of Cambridge, £1,694 over 2 years, to Dr. K. G. Budden for research into the theory of propagation of radiations from artificial satellites; £2,678 over 2 years, to Prof. M. Ryle for the recording and the interpretation of Doppler and Faraday effects in the radiations from artificial satellites; and £11,230 over 26 months, to Dr. F. G. Smith for the measurement of cosmic radio noise by receivers mounted on rockets and satellites.

University of Leicester, £13,006 over 39 months, to Prof. E. A. Stewardson for investigations of solar and stellar soft X-ray emissions.

Imperial College of Science and Technology, London, to Dr. H. E. Elliot, £7,275 over 2 years for satellite measurements of the primary cosmic-ray energy spectron, and £1,500 over 2 years for an investigation into cosmic-ray intensity variations at rocket altitudes; also £7,935 over 3 years to Dr. S. H. Hall for geomagnetic field measurements in the Earth's upper atmosphere.

University College, London, to Dr. R. L. F. Boyd, £8,880 over 3 years for the development and use of photoelectric satellite tracking equipment, and £35,450 over 3 years for rocket research in the upper atmosphere of: (1) atmospheric temperature, density and winds; (2) ionospheric temperature, density and composition; (3) short-wave-length solar radiation; and (4) stellar ultra-violet light.

University of Manchester, to Dr. R. C. Jennison, £15,277 over 40 months for micrometeorite investigations from an Earth satellite (to be carried out at the Nuffield Radio Astronomy Laboratories, Jodrell Bank), and £15,020 over 44 months for low-frequency radio astronomy from an Earth satellite (to be carried out at the Nuffield Radio Astronomy Laboratories, Jodrell Bank); also £2,500 over 1 year, to Prof. A. C. B. Lovell for the tracking of satellites and space probes (to be carried out at the Nuffield Radio Astronomy Laboratories, Jodrell Bank).

University of Oxford, £4,560 over 18 months, to Dr. J. T. Houghton for the development of photoconductive material for satellite measurements of infra-red radiation.

THE BANGOR RESEARCH STATION OF THE NATURE CONSERVANCY

THE new Welsh headquarters of the Nature Conservancy was formally opened on July 20 by Prof. W. H. Pearsall, chairman of the Scientific Policy Committee of the Nature Conservancy. The building, of rough-cast stone and slate-roofed in the local Welsh style, is primarily designed as a laboratory, and its chief function is to act as the Conservancy's research station in Wales. It will, however, also house regional officers mainly concerned with the management of nature reserves and with the cartographic and advisory work of the region. The whole will be under the supervision of Dr. R. Elfyn Hughes, who has been appointed director (Wales), so that the Welsh organization of the Nature Conservancy now resembles that in force in Scotland.

As at present organized, the laboratories are equipped mainly for research in plant ecology. The special equipment is designed mainly for plant analysis and for detailed soil studies, especially the estimation of mineral elements and the properties of clay minerals. A notable feature is the provision of an X-ray fluorescence spectrograph, a new type of apparatus which it is expected will speed up and greatly extend the range of mineral analysis.

The facilities available are suitable for studying the general problems present in all nature reserves, the relation of vegetation to soil and the trends of change affecting these relationships. There are, however, special problems in Wales which are of fundamental importance and of the widest interest to highland Britain as a whole. The great range of rainfall easily accessible in Snowdonia as well as the diversity of rock type make it a most favourable centre for research on the effects of these factors, singly or interacting, upon the development of soils and vegetation. In Snowdonia the interest in this field lies especially in the grasslands and their animal life, and notably in the pattern of grazing by sheep. The evidence already obtained by Dr. Hughes stresses the great importance of the minerals derived from the soil in the interchanges and inter-relations between soil, plant and animal. It also raises the interesting possibility that high rainfall in the west of Britain may have an ameliorative effect as well as that to be expected from soil leaching.

In order to study these complex relations, it has been necessary also to envisage technical advances in the development of statistical methods for the analysis of the vegetation mosaics and their correlation with the complex soil characters, and the diversity of rainfall.

No part of Great Britain has, however, remained unaffected by the impoverishment of flora, fauna and soil induced by human activities in the past. Changes in land-use, even, for example, in the time of mowing a meadow, may have profound effects on the flora and invertebrate fauna. Thus, the increasing historical and archæological evidence accumulating in North Wales about early human settlement also offers considerable scope for developing knowledge of the influence of former land-use on existing vegetation and wild-life. This is a field of research which is scarcely possible elsewhere in highland Britain because of the scarcity of information about the past.

The basic researches which are thus developing owe much to the pioneer work on soils of the late Prof. G. W. Robinson, as well as to the more recent inspiration of Prof. Alun Roberts. They have also profited much from the existence in the University College of North Wales of strong Departments of Agriculture, Botany, Forestry and Zoology, the continued co-operation of which augurs well for the future.

While, in the present stage of investigation, much of the work centres around the general problems of upland and moorland vegetation and soils, there are other centres of developing research in the nature reserves, notably the special mountain floras and faunas, the dune vegetation and invertebrates at Newborough, and the problems presented by the woodland reserves now becoming available. These are likely to offer much scope for development into other fields of investigation as the primary researches mature.

THE DAVID NORTH PLANT RESEARCH CENTRE

THE Colonial Sugar Refining Co. is to build a plant research centre in Brisbane to conduct basic research on the sugar cane plant. The laboratory, costing £300,000, is to be completed by June 1961.

The Company has been well aware that, over the past twenty years, there has been a very considerable increase (more than 50 per cent) in the yield of agricultural productivity per acre. For example, in the United States, that of corn has risen about 80 per cent, milk by 40 per cent and beet sugar by 50 per cent. In contrast to this, the increase in yield per acre of cane sugar in Australia, and probably elsewhere, has risen only by 25 per cent. This suggests ample room for improving the yields of sugar. However, the scope for increasing the yields of sugar by conventional methods may be somewhat restricted as many of the clones which make up the present-day breeding material are the result of perhaps thousands of years of selection for sweetness and low fibre during cultivation by primitive communities and, secondly, the more obvious improvements, mainly associated with disease resistance, have been effected. Future important advances are only likely to be achieved through a background of thorough understanding of sugar cane physiology and genetics.

The laboratory will be known as the "David North Plant Research Centre", after Mr. David Shepherd North, who, as early as 1904, was investigating plant diseases in sugar cane. Later, he became interested in seed germination and breeding of cane. His pioneering work on both diseases and breeding in Australia did much to ensure the success and the stability of the industry.

In 1958, plans for the new laboratory were initiated in collaboration with Dr. H. R. Highkin, Dr. D. Koller and Mr. P. Keyes, of the Earhart Plant Research Laboratories at the California Institute of Technology. The basic plan of the new laboratory is very similar to that of the Earhart Laboratory, which was constructed in 1947–48, under the direction of Prof. F. W. Went. Five air-conditioned greenhouses, each of 240 sq. ft., are to be held at temperatures of the range 10–40° C. These are connected by an atrium to a group of eight constant-temperature rooms occupying 1,500 sq. ft. The rooms encompass a range of temperatures from 40° C. to frost conditions at $-10°$ C.

The constant-temperature rooms are each subdivided into four compartments which are artificially illuminated and provide opportunity to study the interaction of temperature, light intensity and light quality in growth and flowering. Means will also be available to control root temperatures independently of other environmental conditions. Because cane plants grow to considerable height, 20-ft. head-room has been allowed in all of the growing areas.

The remainder of the building is broken into two sections. The entrance to the whole structure is secured through air locks ; change rooms are provided, and visitors and staff alike are required to wear sterile clothing. The main laboratory area, 1,800 sq. ft., provides facilities for biochemical investigations with particular emphasis on tracer techniques.

Studies on the physiology and biochemistry of sugar cane were commenced in 1955 as a joint venture between the Botany Department of the University of Sydney, the Plant Physiology Unit, Division of Plant Industry, Commonwealth Scientific and Industrial Research Organization and the Colonial Sugar Refining Co. The initial work covered studies on the respiration of sugar cane stalks and the germination of sugar cane sets. At the same time, basic studies were undertaken on the mechanism of auxin action in plants. This work showed that the adsorption of pectin methylesterase to the tissues of cell walls could be altered by the addition of auxin and synthetic auxins. Experiments with tissue slices demonstrated that pectin methylesterase could be extracted with dilute salt solutions and that the enzyme was partitioned between the tissue and the extracting solution. The equilibrium concentration of pectin methylesterase in solution was altered by the addition of auxin. Presumably the growth of the plant requires that pectin methylesterase be attached to the wall tissue, and the major action of the auxin is that it should be able to reach the appropriate tissue and cause adsorption of pectin methylesterase and perhaps other enzymes.

The group also investigated the movement of sugars into the storage tissues of cane. The uptake was shown to consist of two processes. The first process was that of diffusion into the outer space of the tissue volume, and was governed by the concentration gradient, equilibrium being attained in about half an hour. The second process continued at a constant rate for about 60 hr. and sugar moved against a considerable concentration gradient. The movement was prevented by anaerobic conditions and a number of metabolic inhibitors. This active uptake of sugar into the inner space is analogous to the accumulation of salts by other plant tissues. It was shown that only sucrose—and not reducing sugars—could be taken into the inner space, but that loss from this space was mainly glucose or fructose formed by hydrolysis, particularly in immature tissue. The turnover time for the sucrose pool for young tissue was about 9 hr.

To make use of these observations and other fundamental data, detailed studies are required of the effects of the environment on growth and the translocation and accumulation of sugars. Comparative studies will be made on different species and varieties within species of the genus *Saccharum*. The central interest will be the ability to store carbohydrate as sucrose.

The genetic make-up of commercial varieties of sugar cane is derived from *S. officinarum*, but virtually all varieties now cultivated carry genes from other species, usually with very low sugar content. Hybridization was carried out to increase vigour, resistance to disease, and to widen the range of climatic conditions in which cane can be cultivated successfully. It is anticipated that the comparative studies on sugar accumulation will provide knowledge of the mechanisms by which canes do or do not store sucrose, and this information can be used as a basis for studies on the physiological and biochemical genetics of sugar production.

The work at the David North Plant Research Centre will also include a comprehensive investigation on flowering in the genus *Saccharum* and several related genera and on problems associated with sterility and with the germination of its seeds. Complementing this programme, more general studies will be undertaken in the field of phytohormonal and chemical control of plant growth.

The research staff will consist of five graduates and assistants. Space will be made available for two or three guest research workers from other institutions to work with the Colonial Sugar Refining Co.'s group.

Other laboratories situated in Brisbane which carry out research on plants are located in several departments of the University of Queensland, at the Cunningham Laboratory of the Commonwealth Scientific and Industrial Research Organization and the laboratories of the Queensland Sugar Bureau. This concentration of research groups should establish Brisbane as a leading centre for research on tropical plants in the southern hemisphere.

K. T. Glasziou

SOME ASPECTS OF AUTOXIDATION

An informal symposium on the "Physico-chemical, Biological and Applied Aspects of Autoxidation" was held during April 4–5 in the Department of Inorganic and Physical Chemistry of the University of Liverpool. The meeting was organized by Dr. N. Uri (Ministry of Agriculture, Fisheries and Food Research Establishment, Aberdeen) on behalf of the Colloid and Biophysics Committee of the Faraday Society, and its host, Prof. C. E. H. Bawn, was its chairman.

On the afternoon of the first day four papers, dealing mainly with physico-chemical aspects, were presented to the meeting. Prof. J. C. Robb (University of Birmingham) spoke about a new method in work on autoxidation of hydrocarbons in the liquid phase. He explained the considerable experimental difficulties that are encountered when the rates of diffusion of oxygen from the gaseous into the liquid phase must be taken into account. A method has been developed in which the oxygen already dissolved is used up during kinetic measurements without the necessity for replenishment. The rate of reaction is followed by the measurement of rise in temperature by means of a thermocouple and a sensitive amplifier. A rise of 10^{-}[illegible] deg. C./sec. can be determined with a time response of about 10^{-}[illegible] sec. The sensitivity of the method enables one to study non-stationary build-up of radical concentration and to obtain quantitative information on rate constants of propagation and termination as well as reactivity of free radicals towards retarders. Autoxidation of *cyclo*hexene and methyl *cyclo*hexene have been studied at temperatures of 40–80° C.

The second paper, which dealt with the initiation phase in the aerobic oxidation of linoleic acid and its esters, was presented by Dr. N. Uri. Evidence was presented suggesting that metal catalysts are important even in the apparently uncatalysed autoxidation. A survey of the effects of heavy-metal stearates and porphyrins indicated that there must be a complex system of initiation involving oxygen–metal complex formation and subsequent formation of free radicals. A reaction scheme was proposed which involved reactions of the metal compound with oxygen, hydroperoxide and substrate and included an inhibitory reaction between metal and free radicals; the latter feature explained an anomalous curve obtained when the rate of reaction was plotted against metal catalyst concentration. Some experiments relating to the effects of environment and chelating on the catalytic activity of the initiaton were described. A brief survey of the effects or various novel free radical acceptors and their theoretical interpretation concluded the paper. If the discussion Dr. Ford (British Petroleum, Sunbury) directed attention to the fact that anomalous initiation curves were observed by him when hæm pigments were used as autoxidation catalysts.

Prof. C. E. H. Bawn introduced his paper on the metal-catalysed oxidation of alkyl aromatics by emphasizing the practical significance of this work in the synthesis of new products and in the deleterious effect causing break-up and degradation of oils and plastics. The oxidation of *iso*propylbenzene to phenol and of *p*-xylene to terephthalic acid are important examples. Recent discoveries have shown that the first stage of the oxidation of *p*-xylene, that is to say, to *p*-toluic acid, proceeds satisfactorily with the conventional cobalt and manganese catalysts, but the second stage requires the presence of bromide. Detailed kinetic results were presented, and a satisfactory mechanism involving initiation by the bromine atom in conjunction with the cobaltous–cobaltic cycle was proposed. Inhibition of the second oxidation reaction in the absence of added bromine was shown to be associated with the formation of phenolic inhibitors which are destroyed by bromine. In the discussion, Dr. Uri pointed out that metal-catalysed initiation in the oxidation of poly-unsaturated fatty acids is more closely related to that generally proposed by Prof. Bawn for aldehydes rather than that proposed for hydrocarbons. In reply to Prof. H. S. Olcott (University of California, Berkeley), Prof. Bawn explained that iodide could not replace bromide. Dr. C. H. Lea directed attention to various salt effects in the oxidative rancidity of fats which are not yet fully explained.

The fourth paper, by Dr. L. Bateman (British Rubber Producers' Research Association, Welwyn), dealt with the oxidation and antioxidant activity of organic sulphur compounds related to rubber vulcanizates. He emphasized that the response of these complex organic sulphides to atmospheric oxidation was not yet fully understood although it was apparent that it differed considerably from that of the parent hydrocarbon polymer. There are some distinctive features: the reaction is catalysed photolytically, by free-radical generators such as azo*iso*butyronitrile, but not by peroxides; α-hydroperoxysulphide initially formed is converted rapidly into sulphoxide and α-hydrosulphide and the reaction is subject to autoretardation. It was shown that sulphoxides formed from monosulphides and thiosulphinates formed from disulphides were efficient inhibitors of olefin oxidation. The effects of substituents on the efficiency of these inhibitors were discussed in detail, and stress was laid on the practical significance of these results in the interpretation of the oxidation characteristics associated with different vulcanizates.

On the second day of the meeting, Dr. J. Friend (Low Temperature Research Station, Cambridge) spoke about some aspects of the biologically catalysed aerobic oxidation of carotenoids. The nature of the enzyme systems responsible for the carotenoid destruction in plant tissue was discussed. These include lipoxidase and lipoperoxidase (recently studied by Dr. Blain) in seedlings and different enzyme systems in chloroplasts and mitochondria prepared from sugar beet leaves; the latter do not require the presence of linoleic acid or diene hydroperoxide. A comparison of the degradation products by enzymic oxidation and non-enzymic oxidation catalysed by linoleate and ferrous phthalocyanine revealed close similarity.

In a paper on the aerobic oxidation of plant phenols and its biological implications, Dr. D. E. Hathway (British Leather Manufacturers Research Association, Egham), exemplified the synthesis of larger molecules from simple phenols by dimerization of semiquinones and polymerization through quinones. Thus, autoxidation of alkyl gallates in alkaline medium leads to ellagate, whereas quinone polymerization occurs during the autoxidation of (+)-catechin. A similar polymer was isolated from *Acacia catechu* heartwood, and it was suggested that it arises as a result of aerobic oxidation in the heartwood tissue. Some further examples of natural phenolic polymers were presented. It was pointed out that aerobic oxidation of catechins and other flavan-3-ols appears to account for the origin of some of the condensed tannins, particularly in tan barks. Brief mention was made of the anti-fungal and anti-viral protective properties of tannin, which, especially in stembark, may have contributed to the successful evolution of existing forest trees.

Prof. H. S. Olcott (University of California, Berkeley) spoke about the effects of tocopherols in autoxidizing systems. He also directed attention to the vitamin E activity of selenium compounds and wondered whether their antioxidant activity is based on the formation of oxides similar to those described by Dr. Bateman in the case of sulphur compounds. The antagonizing effect of free fatty acids on the activity of phenolic antioxidants was contrasted with the synergistic effect of simple amines. With bases such as tri-*iso*-octylamine, more effective synergism was demonstrable with phenolic antioxidants that possess a hydrogen atom adjacent to the phenolic group (γ-tocopherol, butylated hydroxy anisole) than with those in which these positions are substituted (α-tocopherol, butylated hydroxy toluene). Relatively large amounts of aliphatic amines (in the order of 1–2 per cent) act themselves as antioxidants in lard and exhibit an anomalous dependence on temperature in their efficiency. In the discussion of this paper Dr. Barnard (British Rubber Producers' Research Association, Welwyn) confirmed that selenium compounds were found to be more efficient antioxidants than the corresponding sulphur compounds. Dr. E. M. Learmonth (British Soya Products, Puckeridge) directed attention to the instability of purified soybean oil and the synergistic effects of phospholipids. Dr. Uri said that some of the anomalous concentration effects could be explained by the disappearance of the antioxidant by the 'forbidden route' of a chain reaction, and some of the anomalous temperature effects could conceivably be due to chelating of amines with traces of metal porphyrins. Dr. Bateman proposed that certain synergistic effects should be ascribed to a high reactivity of one antioxidant towards $RO_2\cdot$ radicals and a high reactivity of the other towards $R\cdot$ radicals.

Presenting his paper on autoxidation in relation to food, Dr. C. H. Lea distinguished between the major autoxidizible constituent, that is, unsaturated fatty acids, and a wide variety of minor but almost equally important substances; their oxidation is frequently coupled with that of the fats. Dr. Lea went on to survey the main primary and secondary products as well as their effects on flavour, nutritive value and possible toxicity. Finally, a number of factors which influence autoxidative reactions were discussed, including both pro-oxidant and anti-oxidant effects in general, the action of hæm protein catalysts and lipoxidase, and finally the variable effects of ascorbic acid which, depending on the environment, acts either as pro-oxidant or as anti-oxidant.

The last paper of the meeting was that of Dr. L. A. O'Neill (Paint Research Station, Teddington) on problems of autoxidation in the paint industry. He pointed out that paints which depend on the autoxidation of a drying oil or a polymeric derivative thereof, such as an oil-modified alkyd resin, are still the most widely used class. The oxidation involves the formation of —C—C— polymers via conjugated peroxides. Emphasis was placed on the interesting distinction between the catalytic action of cobalt compounds with oxidation spreading from the surface into the body of the medium and that of lead compounds with uniform oxidation of the bulk of the oil. Oximes are used as temporary antioxidants for storage in containers and afterwards lost from the surface film. Mercaptans prevent the oxidation from proceeding towards degradation. The nature of 'yellowing' on prolonged ageing, which is accelerated by ammonia and other bases in the atmosphere, is not yet fully understood.

N. URI

AVERAGE WATER VAPOUR CONTENT OF THE AIR

IN a recent memoir issued by the Meteorological Office, J. K. Bannon and L. P. Steele outline the first use of humidity observations made with radiosondes to describe, on a nearly world scale, the variation with height of the mean water vapour content of the atmosphere (Air Ministry: Meteorological Office. Geophysical Memoirs No. 102: Average Water-Vapour Content of the Air. Pp. ii+38. (M.O. 631*b*). London: H.M. Stationery Office, 1960. 8*s*. 6*d*. net). Previous work of this nature was necessarily carried out by extrapolating from surface values with empirical formulæ, deduced from mountain observations, for the rate of decrease with height.

The data, which are for the period 1951–1955, are presented in the form of charts for January, April, July and October of isopleths of the average weight of water vapour in decigrams above 1 square centimetre at the Earth's surface and the isobaric surfaces for 850 mb. (about 1·5 km. height), 700 mb. (about 3 km.) and 500 mb. (about 5·5 km.). Surface pressure is about 1,000 mb.

The authors necessarily devote much space to a detailed discussion of the observations and of the difficult problems involved in reconciling observations made with different types of radiosonde and allowing for instrumental defects such as lag.

The most obvious feature of the charts at any on level is that water content is highest over the equatorial rain forests and India in the summer monsoon, and least over the polar regions. Values are notably low for the latitude over the Sahara, where they are about the same as over Europe, but the other great desert areas are not very prominent in the run of the isopleths. Comparing the charts at different levels, it is clear that at all seasons, and over all areas on the average, half the water vapour content of the atmosphere is below 850 mb., far below the corresponding level for air at 500 mb. The highest value is over India in the summer monsoon, when the atmosphere holds 64 decigrams of precipitable water. Above the equatorial belt there is about 50 decigrams. Over the British Isles in winter the amount is about 11 decigrams and in summer 24 decigrams.

The charts permit rough calculations to be made of the ratio of precipitation to storage of water vapour in the atmosphere. Over the Earth as a whole the store is equivalent to nine days rainfall, but over wet cool regions such as the British Isles in winter the average store is equivalent to only about three days rainfall. Such differences in the storage ratio reflect differences in the manner of production of rain, which is mainly by convection of 'local' water vapour over the hot regions and by advection from over the oceans in cool ones.

FREEZING AND DRYING OF BIOLOGICAL MATERIALS

IN recent years much has been said about the rift between science and the humanities. Nevertheless, the majority of scientists are interested in history or literature, music, drama or art, while most students of the humanities use products of science and notice the impact of others on the world at large. The widening gap between different scientific disciplines may be more serious. A stage is approaching when biologists and physicists will no longer understand one another whether they try to communicate orally or by writing. Several attempts to bridge this gap have already been made by those who investigate the effects of low temperatures and of desiccation on living cells and tissues and on their products.

The publication "Freezing and Drying of Biological Materials" is based on a conference held at the New York Academy of Sciences in October 1959[*]. It forms a valuable sequel to two colloquia organized by the Institute of Biology in 1951 and 1958, to the discussion at the Royal Society in 1957, and to Prof. D. Keilin's Leeuwenhoek Lecture in 1958. This is not a book for beginners. Dr. H. T. Meryman is over-optimistic in saying that a stage of simplification has been reached in cryobiology. Prof. B. Luyet is nearer the truth in thinking that the biologist who works at low temperatures is in "a chaos of disequilibrium and disorder". Dr. Luyet has, himself, thrown further light on the phase transition in gelatin gels and in solutions of glycerol, sugars and other biological media at low temperatures. Dr. J. L. Stephenson has continued his mathematical analysis of the process of crystallization in model biological specimens during rapid freezing. Prof. L. Rey admits that it is almost impossible to measure the eutectic temperatures of natural substances; nevertheless, he assesses the 'eutectic requirements' of biological materials in order to reduce damage after thawing or reconstitution from the dry state. Dr. C. V. Lusena finds that rates of formation, dissolution and redistribution of ice are very slow in solutions of glycerol below −40° C. Dr. A. C. Taylor reports that few cells from human conjunctiva or avian skin survive rapid cooling in one stage to −78° or to −120° C. or when the formation of ice is accelerated by use of hydrostatic pressure. Dr. P. Mazur thinks that when certain micro-organisms are cooled rapidly in the range below −15° C. ice crystals in the frozen medium could seed the supercooled interior of the cells by passing through minute pores in the cell membrane; damage, which occurs when slow thawing follows rapid cooling, might be due to migratory recrystallization of the intracellular crystals.

---

[*] *Annals of the New York Academy of Sciences*. Vol. 85, Article 2: Freezing and Drying of Biological Materials. By Harold T. Meryman and 12 other authors. Pp. 501–734. (New York: New York Academy of Sciences, 1960.)

Contributions from authors absent from previous conferences are particularly welcome. Dr. J. Levitt describes freezing injury in plants; but his attempt to produce a single theory to explain the cause of damage in cells of animals and plants is less successful. Dr. A. P. Rinfret has studied factors affecting the erythrocyte during rapid freezing and thawing in the absence and the presence of glycerol and other protective substances. Dr. A. L. Hopkins has used radio-frequency spectroscopy to study biological media, human erythrocytes and frog ventricles at temperatures between 0° and −100° C. In a striking paper, Dr. H. Fernández-Morán describes the properties of liquid helium II and its use for preparing specimens of mammalian tissue for electron microscopy. He claims that his technique gives superior preservation of macro-molecular structures. Cytologists will need considerably more evidence and illustrations to convince them that freezing at −272° C. is necessary when subsequent staining is carried out at −150° C.

Dr. T. W. G. Rowe, in an excellent account of the theory and practice of freeze-drying, employs two useful terms: the 'Torr', a measure of vacuum equivalent to a pressure of 1 mm. mercury, and the 'Lusec', the rate of leakage under a pressure difference of 1 atmosphere of 1 litre/sec. at a pressure of 1μ. Principles of freeze-drying are also elucidated by Dr. H. T. Meryman and Dr. R. I. N. Greaves. Dr. Greaves discusses factors involved when viability of bacteria and other living cells is to be preserved by desiccation and stresses the importance of the composition of the medium surrounding them. Dr. Meryman and Dr. E. Kafig are the first to have successfully preserved mammalian cells by freeze-drying. Rat erythrocytes were intact and bull spermatozoa resumed motility after drying and reconstitution under the special conditions of their experiments. It is hoped that this interesting result with bull spermatozoa will be confirmed in other laboratories.

A number of typographical errors have been noted; the figure legend on p. 523 is incorrect. Verbal efflorescences such as "organoleptic properties" (p. 527) to describe meat, "operational complementarity" and "sequentially arrested states" (p. 690) will do little to bring physicists and biologists together and would drive Mr. Thurber to his psychosemanticist. The editors are, however, to be congratulated on the speed with which they have published the report of this important conference.

AUDREY U. SMITH

U.S. NATIONAL ACADEMY OF SCIENCES–NATIONAL RESEARCH COUNCIL

ANNUAL REPORT FOR 1958–1959

THE annual report for 1958–59 of the National Academy of Sciences–National Research Council includes the review of the president, Dr. Detlev Bronk, reports on the autumn meeting, 1958, and annual meeting, 1959, of the National Academy, the Treasurer's report, list of publications and reports on the activities of the Academy and the Research Council, including those of the several Divisions, those not assigned to a Division, of the Office of International Relations, of the Office of Scientific Personnel, and of the United States National Committee for the International Geophysical Year (pp. viii+224. Washington, D.C.: Government Printing Office, 1960. 70 cents). The president in his review stresses the increasing concern of the Academy–Research Council with international scientific activities. The new Committee on Oceanography, an outgrowth of the International Geophysical Year, completed a report on the status and needs of all phases of oceanography and its opportunities, which has already stimulated greater interest in oceanography and support for oceanographic research, including provision by the National Science Foundation of a new research vessel. As a result of a conference held under the auspices of the Academy and the President's Science Advisory Committee to consider how science and technology can be used more effectively by the International Co-operation Administration in its programmes of foreign assistance, the Academy was requested to study the possibilities for such assistance to the regions of Africa south of the Sahara and north of the Union of South Africa.

During this first formative year of the National Aeronautics and Space Administration, the Space Science Board, established in June 1958, after securing programme recommendations from a broad cross-section of the scientific community, sought to develop a short-range space science programme.

Physics, chemistry, mathematics, astronomy, geology, geophysics, psychology and biology are all represented on the Board. Many biologists are planning for research undertakings in outer space and to provide a forum for their discussions and planning an Armed Forces–National Research Council Committee on Bio-astronautics has been established.

The Committee on Fire Research has recently broadened the scope of its interests to include consideration of the causes and control of all unwanted fires, such as forest fires, and publication of *Fire Research Abstracts and Reviews* as a periodical was commenced. A Research Correlation Conference on "Noise Control in Buildings" was sponsored by the Building Research Institute and a committee set up for the study of agricultural pests and their control. Two temporary committees were appointed to supplement the work of the Materials Advisory Board, one to consider and define the more promising areas of research in solid-state physics and metallurgy, and the other to deal with the organization and support of materials research in the universities, industry and government.

The Division of Medical Sciences commenced a survey of needs in tropical medicine, and its Committee on the Cardiovascular System is seeking to stimulate interest in research into the central nervous control of circulation, but the Committee on Infectious Diseases and Chemotherapy is being dissolved to make way for a more fundamentally oriented group. The activities of the Division of Chemistry and Chemical Technology markedly increased, particularly in the international field; the Division of Engineering and Industrial Research was also much occupied, and its Committee on Ship Steel and Ship Structural Design continued to assist the research programme of the inter-agency Ship Structure Committee by formulating research programmes in these fields. These include a study of the influence of metallurgical structure on the brittle behaviour of ship steel, a comparison of the influence of manganese, carbon and other elements on notch-impact properties, and efforts to increase knowledge of the response by ships to ocean waves and of brittle fracture mechanics.

The Office of International Relations has worked vigorously to foster exchanges of scientists between the United States and the U.S.S.R. and to facilitate travel there of United States scientists. A programme of reciprocal exchanges was negotiated between the Academy and the Academy of Sciences of the U.S.S.R. and arrangements were made for the participation of United States scientists in more than thirty international scientific meetings.

RECRUITS TO TEACHING IN GREAT BRITAIN

An inquiry by F. W. Land, of the University of Liverpool, was undertaken primarily in order to investigate the factors which were restricting the recruitment of a sufficient number of students in training colleges who were able and willing to teach mathematics and science*. This problem must be looked at as a facet of the larger problem of producing the whole body of teachers who should have, between them, a proper balance of subject interests. Although smaller in number, the trained graduates from universities take a role in this balance which, in many respects, is crucial, since they provide the greater part of the staffs of grammar schools from which are recruited the majority of the training college students.

The problem of university teacher-training departments is that mathematics and science graduates are not coming forward for training as teachers, whereas the training college problem is that those who are electing to train as teachers are reluctant to study mathematics and science. The Association of Teachers in Colleges and Departments of Education report of 1956 made it clear that this can only be brought about by a manifold increase in the number of mathematics and science graduates coming forward to train for service in both grammar schools and training colleges. This, in turn, depends on the ability of the universities to recruit more mathematics and science students and upon the willingness of industry to curb its seemingly insatiable demand for mathematics and science graduates.

Any future increase in the number of science undergraduates will depend on the ability of schools to supply further recruits able to undertake university courses, and this, in turn, is dependent upon a supply of science teachers. For the time being, until the critical supply of teachers has been rectified, industrialists should be asked how many of the posts now being filled by graduates could be filled with less highly qualified persons without substantially reducing industrial efficiency.

Mathematics and science pose problems for the training colleges which are of a different nature. Throughout the infant and junior schools almost all teachers are called upon to teach arithmetic. In secondary schools there is no possibility for years of having enough properly qualified teachers to provide specialist mathematics teachers for all children, and it is a debatable point whether studies such as English and mathematics, which are basic to all other studies, should be taught by specialists throughout the secondary schools. Most secondary teachers must expect to teach some arithmetic at least, even if the more specialized parts of the mathematics syllabus are in the hands of specialists. For this reason the arithmetical competence of all training college students is a matter of direct and intimate importance to their teaching.

Science teaching will be much more in the hands of the specialists. In secondary schools, specialists with responsibilities for laboratories must teach the greater part of science. In many junior schools in Britain almost no science is taught at all. Although it is highly desirable that more science be introduced into junior schools, it will not be highly specialized science calling for special qualifications, and any well-educated teacher ought to be able to cope with junior school science as he is expected to cope with junior school geography, history or handwork. The demands of schools are for an *adequate* proportion of students to be well qualified to serve as science specialists, and, in addition, it is desirable that *all* teachers should be informed about the basic nature of the scientific developments which are such a common feature of the environment in this second half of the twentieth century.

---

* Recruits to Teaching: a Study of the Attainments, Qualifications and Attitudes of Students entering Training Colleges. By F. W. Land. Pp. 83. (Liverpool: The University Press, 1960.) 7s. 6d. net.

For all students, standards to be desired are: sufficient mastery in both English and mathematics to qualify them as competent to teach the subjects, a generally balanced education which includes a fair knowledge of and interest in all the main subjects of the curriculum, including chemistry and physics as well as history and geography and art and music, together with a more specialized interest in a particular subject which has been studied to the standards for examination at Advanced Level of the General Certificate of Education, and which will be their own individual contribution to the vitality of the teaching in their school. The interests of the schools require that the more specialized main studies should be so distributed among the teachers that the staffs of schools are not unduly biased in their interests and include representatives of all the main intellectual disciplines.

These desirable standards are fulfilled in respect of English. The fact that the outlook for English is so healthy with entrants to training colleges is a reflexion of the fact that five times as many women honours graduates in English are being fed into schools by university departments as correspondingly qualified mathematicians.

In arithmetic and mathematics the position is most unsatisfactory. In mathematics only just over half the students enter training colleges with passes at Ordinary Level of the General Certificate of Education, women students rate it tenth on their lists of interests and 44 per cent say either that they dislike it or they derive no enjoyment from it. The Vernon Test discloses such gross shortcomings in simple arithmetic that many students will have to spend time on basic arithmetic in the course of their training. In Land's investigation only 193 women students out of 1,880 have elected to study mathematics as a main subject.

For the 90 per cent of students who are not taking main mathematics, provision must be made to give them ample opportunity to prepare themselves for whatever arithmetic and mathematics teaching comes their way. Approximately half of these seem to have sufficient competence to begin on a course which should have a two-fold aim. A necessary part of this course should be to interest them in using the mathematical skills they have, so that they begin to value their irreplaceable contribution to the understanding and appreciation of the world around them. This calls for the exercise of considerable imagination and versatility, and, at present, many training colleges do not find sufficient time on their time-tables to enable this task to be attempted with any hope of success. The other part of their course will be more closely pedagogical and devoted to 'methods of teaching'.

For the other half of the students, these two courses need to be preceded and accompanied by a further course in basic arithmetic and mathematics. Such a course should begin with the assumption that there is no confident facility with number work. It must also take into account that achievement and understanding have been limited to arithmetic and that there is no background of appreciation of mathematical ideas to build on. It must start with the acceptance of shortcomings in the powers of visualization of mathematical concepts, and, so far as possible, begin with simple arithmetical processes and build up some picture of mathematical development without much recourse to abstract ideas, formulæ or formal geometry.

The staffing needs of mathematics ought to be reassessed. That about a quarter of the women's colleges have been without full-time mathematics lecturers has always seemed, in Land's words, "to have been scandalous".

ASSOCIATION BETWEEN AURORÆ AND VERY LOW-FREQUENCY HISS OBSERVED AT BYRD STATION, ANTARCTICA

By L. H. MARTIN, Dr. R. A. HELLIWELL
Radioscience Laboratory, Stanford University, Stanford, California
AND
K. R. MARKS
U.S. Antarctic Research Program, Washington 25, D.C.

OBSERVATIONS during 1959 at Byrd Station, Antarctica (lat. 70·5° S. geomagnetic), show a close association to exist between auroræ and certain very low-frequency hiss. The hiss usually occurs in a broad band with a centre-frequency of about 8 kc./s. The intensity and band-width vary with ionospheric absorption and may also vary with the intensity of the auroræ. Under conditions of extreme ionospheric absorption, the intensity of the hiss drops to undetectable levels even in the presence of intense and active auroræ. There are some indications that the centre-frequency of this auroral hiss may be related to the type of aurora; in particular, a centre-frequency of 9·6 kc./s. appears to be associated with red aurora. The average field intensity of the auroral hiss lies between 1 mV./m. and 3 mV./m.

The hiss was received with equipment designed for the study of whistlers and related very low-frequency phenomena. This equipment consists essentially of a large vertical-loop antenna matched to a wide-band (150 c./s.–30 kc./s.) audio amplifier. The signals received were automatically recorded for 2 min. each hour. Auroral data were obtained visually as part of the regular International Geophysical Year programme.

The close association between the occurrence of auroræ and very low-frequency hiss on frequencies greater than 4 kc./s. can be seen from the contingency tables.

Table 1. OCCURRENCE AND ABSENCE OF AURORÆ AND VERY LOW-FREQUENCY HISS ABOVE 4 KC./S.

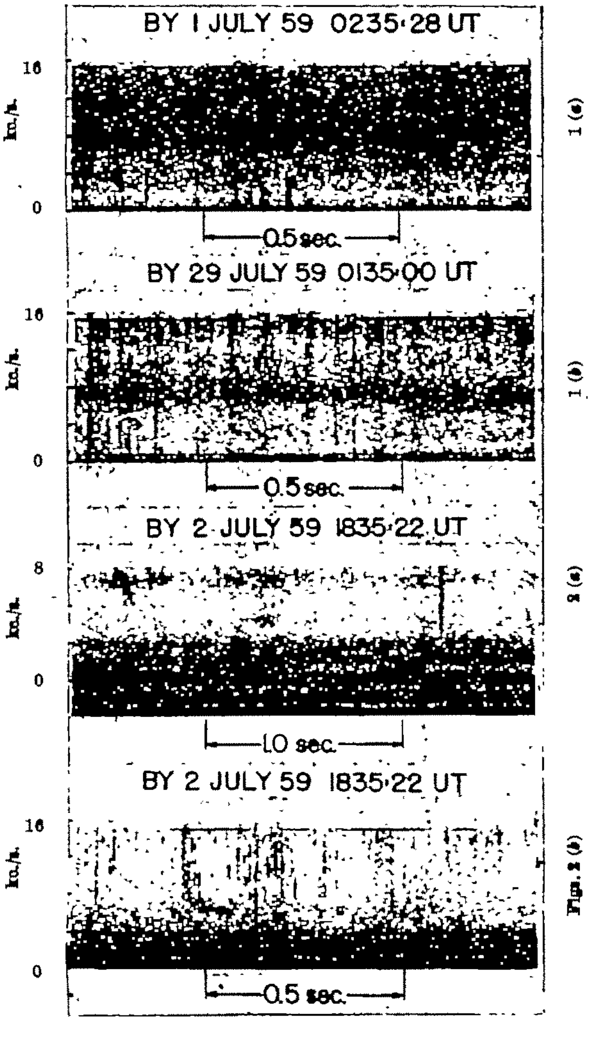
		Hiss above 4 kc./s.	
		Yes	No
Auroræ	Yes	213	18
	No	31	334

The contingency table of actual results (Table 1) may be compared with the equivalent random table (Table 2), which shows the results that would be expected if there were no association whatever between the very low-frequency hiss and auroræ.

Table 2. RANDOM CONTINGENCY TABLE OF OCCURRENCE AND ABSENCE OF AURORÆ AND VERY LOW-FREQUENCY HISS ABOVE 4 KC./S.

		Hiss above 4 kc./s.	
		Yes	No
Auroræ	Yes	93	138
	No	151	214

This comparison shows the significant association between the occurrence of the very low-frequency hiss and auroræ. A statistical (χ^2) test on the above tables gives $\chi^2 = 418$ for three degrees of freedom, thus strongly supporting the inference drawn from an inspection of the 'Yes—Yes' figures.



Figs. 1 and 2

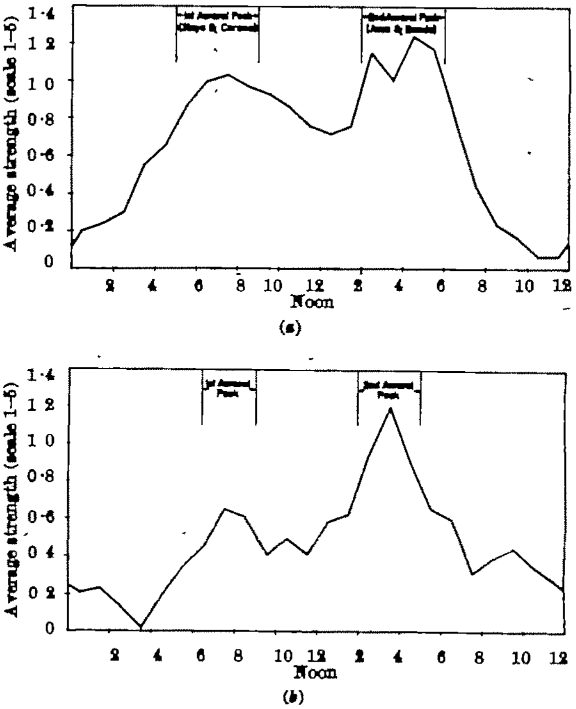


Fig. 3. Diurnal variation of hiss at frequencies greater than 4 kc./s. at Byrd Station. (a) July 1959; (b) August 1959

As Table 1 shows, hiss occurring on a frequency greater than 4 kc./s. cannot always be associated directly with auroræ, nor can visible auroræ always be associated with hiss. The 31 occasions when hiss was observed but no auroræ reported coincide with periods when visual observations were not possible due to cloud cover or bright moonlight conditions; it is probable that auroræ did occur on these occasions and the discrepancy is not regarded as significant. The 18 occasions noted when auroræ were observed without hiss occurring can be attributed to complete absorption of the hiss signal in the lower ionosphere during blackout conditions. During the prolonged ionospheric storm of July 10–16, 1959, which was accompanied by considerable auroral activity, no hiss was observed during the periods of complete ionospheric absorption. The hiss signals returned simultaneously with the return of high-frequency echoes on the vertical-incidence ionosonde.

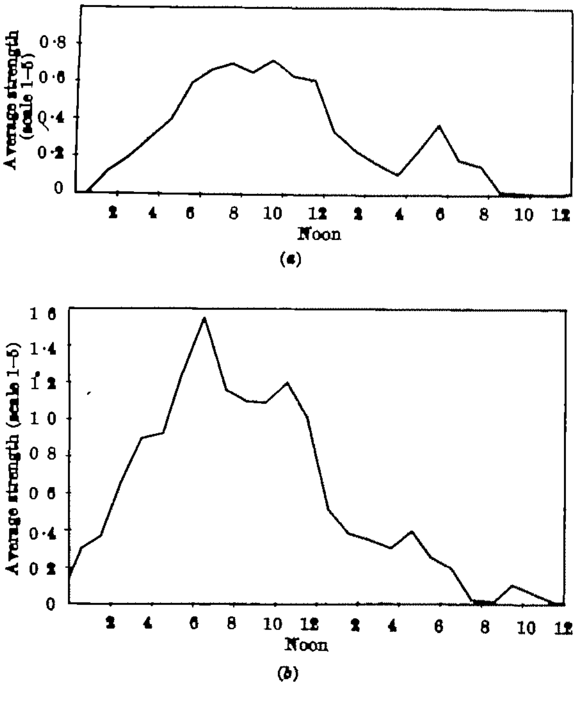
Auroral hiss as observed at Byrd Station is different in character from the usual very low-frequency hiss observed at this Station. The normal hiss band lies at frequencies less than 4 kc./s. and the hiss is usually associated with 'chorus', a mixture of rising and falling tones. Figs. 1*a* and 1*b* show a typical sonagram of the 'auroral' hiss, and it can be seen that the greater part of the energy is concentrated at frequencies greater than 4 kc./s. and that the hiss extends above 16 kc./s. Figs. 2*a* and 2*b* show a typical sample of the normal very low-frequency hiss received at Byrd Station. Here the greater part of the energy is concentrated at frequencies less than 4 kc./s. and the hiss is accompanied by 'chorus'. The lower-frequency limit of the hiss appears to extend below 150 c./s., which is the low-frequency cut-off of the equipment.

The diurnal behaviour of the 'auroral' and the normal very low-frequency hiss are significantly different. The average diurnal variation of the 'auroral' hiss for July and August, 1959, plotted in Figs. 3a and 3b shows two diurnal peaks, each coinciding with periods of maximum auroral activity. The diurnal behaviour of all other hiss for these months is plotted in Figs. 4a and 4b. These curves show one significant peak and closely follow the diurnal pattern of 'chorus' activity as plotted in Figs. 5a and 5b.

Figs. 3a and 3b show two diurnal maxima, each corresponding to different types of auroral activity. It has been suggested[1,2] that these bi-diurnal peaks result from different diurnal distribution and characteristics of auroræ occurring in two distinct auroral zones, an inner zone, about 10° from the geomagnetic pole, and an outer zone, about 20° from the geomagnetic pole. The diurnal peak of auroral activity of the inner zone coincides with the diurnal peak in chorus and very low-frequency activity at frequencies less than 4 kc./s. Further study of this coincidence is required before any great significance can be attached to it.

Very low-frequency noise associated with auroræ has been previously reported by other workers. The simultaneous occurrence of sub-visual aurora, observed with a sky-scanning photometer, and 4·6 kc./s. noise observed on a narrow-band receiver at lat. 42° S. geomagnetic as reported by Duncan and Ellis[3] are not inconsistent with the observations at Byrd Station.

The origin, or origins, of very low-frequency hiss and associated emissions is not yet understood. Hypotheses have been advanced based on: (1) selective travelling-wave amplification in the outer ionosphere[4]; (2) Čerenkov radiation[5]; and (3) proton gyro-resonance[6]. The first two are similar in many respects and do not appear to be inconsistent with the observations reported in this article. However, the proton gyro-resonance hypothesis would seem to be applicable only to hiss occurring at frequencies less than that of proton gyro-resonance as pointed out by Aarons *et al.* Since the dominant hiss associated with auroræ occurs at frequencies greater than 4,000 c./s. and the maximum possible proton gyro-frequency is about 800 c./s., it appears that this hypothesis cannot account for the 'auroral' hiss observed at Byrd Station.



(a)

(b)

Fig. 5. Diurnal variation of 'chorus' at Byrd Station. (a) July 1959, (b) August 1959

Further studies of available results are in progress, and it is expected that the occurrence and frequency distribution of the hiss bands throughout one year will be established. Further field observations should seek to determine the detailed relationships between the spectral characteristics of hiss and aurora. In addition, it is important to determine the spatial distribution of hiss with geomagnetic latitude. This might be accomplished using suitable direction-finding techniques or spaced-station studies along a line of geomagnetic longitude.

The very low-frequency observations at Byrd Station were made by K. R. Marks, and subsequent analysis of the recorded tapes was carried out at the Radioscience Laboratory, Stanford University, under National Science Foundation Grant 9511. The auroral data were compiled from observations by Mr. Marks and reports were issued by the U.S. Antarctic Research Program of the National Science Foundation.

PRECISION INTERCOMPARISONS OF LEAD ISOTOPE RATIOS: BROKEN HILL AND MOUNT ISA

By F. KOLLAR, Prof. R. D. RUSSELL and T. J. ULRYCH
Geophysics Laboratory, Department of Physics, University of British Columbia, Vancouver, 8

VARIATIONS in the isotope ratios of lead as observed in Nature are being used to a steadily increasing extent for such problems as determining the mode of emplacement of sulphide ore bodies, estimating the absolute ages of deposition of certain mineral deposits and as a means of obtaining geochemical information about the distribution of uranium, thorium and lead in the outer parts of the Earth. The precision with which such measurements can be made is variable, and it is difficult to state an overall average, but uncertainties in a single analysis ranging from a few tenths of 1 per cent in the various ratios up to nearly 1 per cent certainly occur. As more and more sophisticated methods for analysing these data are developed the interpretations become more and more dependent on the available precision. We have recently constructed a mass spectrometer and have developed techniques which enable lead isotope ratios to be compared with a precision substantially better than that previously obtained. It is the purpose of this article to show some examples of the precise intercomparison of lead samples and to make a few preliminary interpretations of the results obtained.

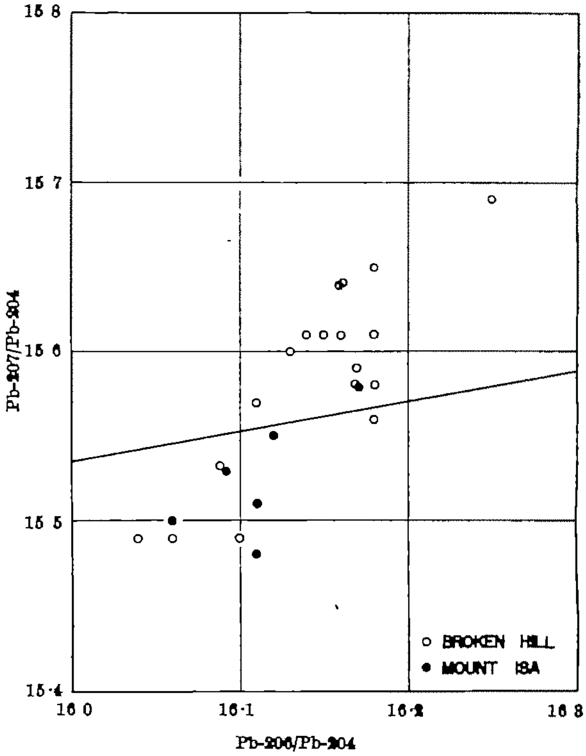

Fig. 1. Measured lead isotope ratios by the University of Toronto. The solid line is the conformable lead curve selected by Russell and Farquhar (in the press)

All the measurements described in this article were made on a 12-in. radius, 90° sector-type, direction-focusing mass spectrometer constructed in our laboratory. Apart from the fact that this instrument makes use of transistor and magnetic amplifiers in the various power supplies[1], it is not substantially different from the usual instruments of its size. Principal differences that contribute towards increased precision are the stability of the filament emission control, which is somewhat better than in many instruments, and the use of a servo voltmeter to measure the ion currents, which enables us to make a peak height measurement with a precision much greater than we could obtain by measuring the record obtained with a chart recorder. Even with this precision and stability we are able to observe small variations in the ratios measured in a single sample from day to day. These variations are about 1/10 of 1 per cent. In order to minimize this effect we have compared each sample with a standard by observing alternatively two pairs of the sample spectra and two pairs of the standard spectra. Our procedure has been to compare the standard with one sample, then to compare this sample with a second, and finally to compare the second sample again with the standard. This gives a closed loop around which the deviations should sum to zero. In the measurements we obtain there is a closure error which is distributed among the measurements in the loop. Thus to obtain values

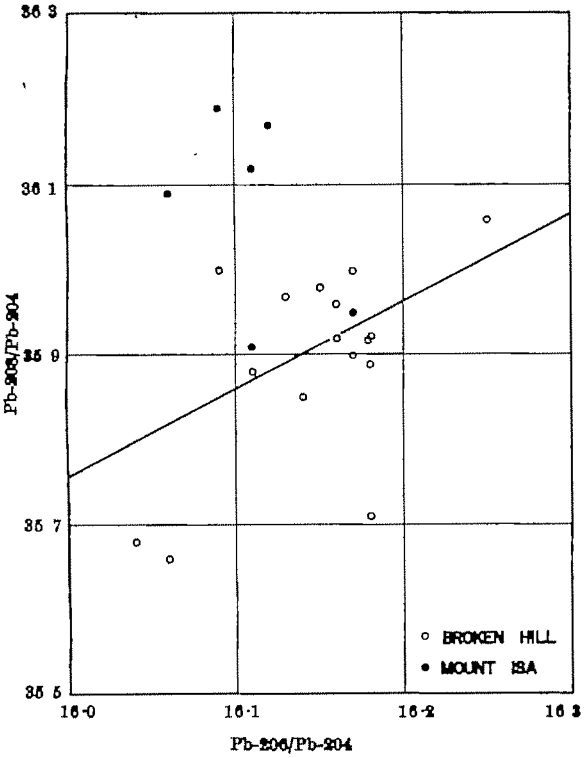

Fig. 2. Measured lead isotope ratios by the University of Toronto. The solid line is the conformable lead curve selected by Russell and Farquhar (in the press)

for two samples we require the equivalent of six separate analyses. However, this additional effort has been well worth while in the increased precision obtained.

It should be remarked that the intercomparison has been made possible by having rather pure samples of lead tetramethyl made by purifying the products of the usual Grignard reagent reaction in a vapour phase chromatographic column. Having pure samples increases the precision in a number of ways. Specifically, we are able to reproduce very closely the pressure and composition of the gas in the mass spectrometer source region and we are able to operate at lower mass spectrometer pressures than we would otherwise be able to do, thereby reducing the effect of pressure scattering. Despite these precautions the tailing due to pressure scattering is still significant and we make a correction for this in our final results. This correction ordinarily amounts to about 0·06 per cent at the adjoining mass.

Measurements made in this way are shown in Table 1 for samples from the conformable layer Broken Hill, New South Wales, Australia, and from Mount Isa, Queensland, Australia. Both these localities have previously been investigated by Russell, Farquhar and Hawley[3] and by Stanton and Russell[4]. The results of the previous analyses are shown in Figs. 1 and 2, where it is clear that it is impossible to observe any convincing relationship between the Mount Isa and the Broken Hill samples, and which show very clearly the magnitude of the spread in the existing measurements on these samples. Figs. 3 and 4 show the results of analyses made at this University with the new instrument and technique. The difference in precision is very striking. In particular, the cluster of points presenting the

* Samples indicated were measured from the recorded chart.

Broken Hill analyses in Fig. 3 is just a factor of 10 smaller than that previously reported. Moreover, the distinction between the Mount Isa and the Broken Hill samples is now clear. The Broken Hill samples were calculated from peak heights measured with a Brown chart recorder, and are therefore slightly less precise than the Mount Isa results, which were measured directly from our servo voltmeter.

Table 2 lists the analyses of our comparison sample No. 1, which is identical with Toronto sample No. *T*-1003 and which in turn has been widely circulated as an inter-laboratory standard. It can be seen that even on an absolute basis the reproducibility over a period of several weeks is quite good. It is also apparent that the reproducibility, particularly of the lead-208 value, is better for samples measured with the servo voltmeter.

Although it is not primarily our intention to discuss the interpretations of these analyses in this article,

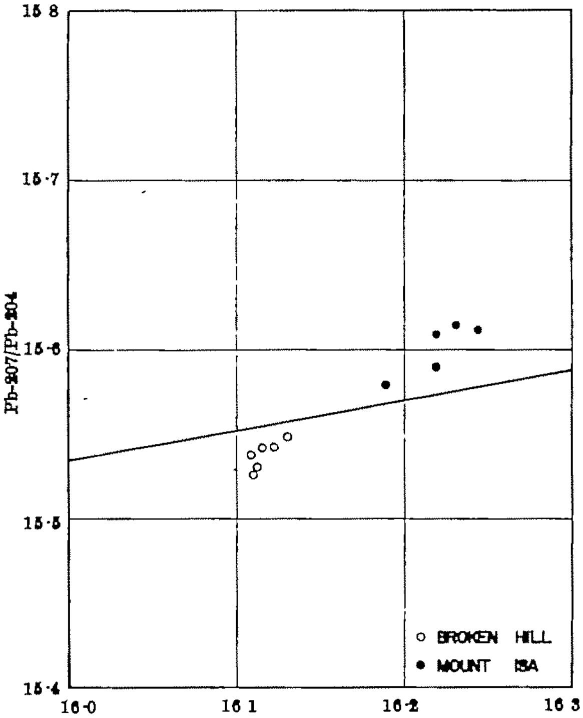

Fig. 3. Measured lead isotope ratios by us. The solid line is the conformable lead curve selected by Russell and Farquhar (in the press)

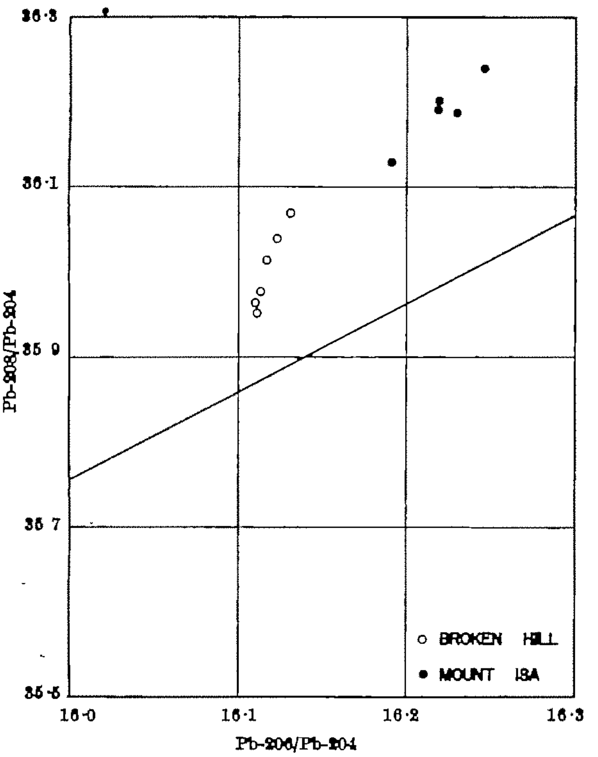

Fig. 4. Measured lead isotope ratios by us. The solid line is the conformable lead curve selected by Russell and Farquhar (in the press)

the following points seem very clear. Stanton and Russell[3], and Cahen *et al.*[4] have suggested uniformity in isotopic composition as one of the criteria for non-anomalous leads. It can be seen that the lead-207/lead-204 and lead-206/lead-204 isotope ratios for the Broken Hill samples differ from their average value by less than 0 07 per cent. These samples are obtained from a 200 square mile area of the conformable lead-bearing deposits at Broken Hill. Such extreme constancy for lead isotope ratios for a region this size has never been demonstrated before.

The ratio lead-208/lead-204 is not nearly so constant, and we feel that the range of variation in this ratio exceeds the experimental error, which, judging from Table 2, should be no worse than for the other ratios. Note that this variation cannot be explained by an uncertainty in the lead-204 abundance. Our tentative interpretation is that the Broken Hill conformable leads have been contaminated by small amounts (0·2 per cent) of radiogenic leads formed from an environment with a uranium/thorium ratio three times the mean crustal or subcrustal value. The largest contamination is observed in samples No. 30 and No. 44, which occur farthest from the north-east–south-west line through Broken Hill parallel to the structural trends of the district. A similar trend is suggested by the measurements by Russell and Farquhar, but is obscured by the larger uncertainties of the measurements.

The Mount Isa samples are less constant, and we are confident that the variation among these samples is significant. Moreover, these samples do not fit on the identical growth curve that would be chosen on the basis of the Broken Hill samples. However, if the less radiogenic samples are considered from each group, they fit a common growth curve to within about 0·15 per cent. These two mining areas are about 800 miles apart and this lends some support to the suggestion that these leads have been derived from depth by relatively simple processes, as has been suggested by Stanton[5]. The relationship among the Mount Isa samples is one that can be explained on the assumption that these are slightly anomalous leads being contaminated by thorium and uranium leads in their crustal environment. It is apparent that the Mount Isa leads are younger than the Broken Hill leads by an amount not exceeding 80 million years and probably not greater than 40 million years if the least radiogenic sample from each location is considered.

We are at present undertaking a series of measurements in an effort to find out whether suites of anomalous leads lie closely on straight lines as suggested by Russell, Farquhar and Hawley in the reference cited above, whether conformable leads as defined by Stanton lie as precisely on a single growth curve as preliminary measurements have suggested and whether samples of the same age do lie on isochrons as postulated originally by Gerling, Holmes and Houtermans.

Technical assistance of J. L. Allard and P. H. Neukirchner is acknowledged with thanks. The samples were supplied through the kindness of Dr. H. F. King, Dr. R. M. Farquhar and Dr. R. M. Thomson. This work has been supported by the National Research Council of Canada and the Geological Survey of Canada.

POTENTIOMETRIC STUDY OF PRIMING PAINTS FOR METAL

By DR. N. R. BHARUCHA

Research Association of British Paint, Colour and Varnish Manufacturers, Paint Research Station, Teddington

SINCE corrosion is an electrochemical phenomenon it is reasonable to expect that a study of potentials on the surface of a corroding metal would yield valuable and interesting information concerning the corrosion process. Useful information has already been obtained from the study of changes in the potentials of metal surfaces corroding in an aqueous environment[1–8].

The presence of single coats of oil paints on the metal surface does not interfere with the process of potential measurements as both water and dissolved oxygen permeate sufficiently rapidly through the paint film. The effects of the coating on the corrosion reaction may hence be determined. Potentiometric examinations of painted metal specimens have been carried out by several authors[9–14]. The measurement of such compromise potentials has drawbacks. The potential/time curves of specimens exposed to corrosive environments are generally subjected to random fluctuations. The results obtained are only qualitative, since the interpretation of the curves must in all cases depend not upon the actual values but upon the direction of the drift of such potentials with time. Furthermore, depending on the anodic and cathodic polarization characteristics of the metal, a measured potential may be associated with either a very low or a very high anodic current density. The measurement of such potentials also does not provide any conclusive information on the nature of any corrosion inhibition, that is, whether anodic or cathodic.

A new method has been devised to provide data capable of quantitative interpretation, measuring individually the potential changes of anodic and cathodic areas of a partially painted test specimen. Since painted areas are generally found to be cathodic with respect to unpainted steel areas[15,16], a single specimen half-coated with a paint (primer) may be looked upon as forming a 'contact couple' when immersed in a corroding environment. A schematic representation of such a contact couple is shown in Fig. 1. The current lines are seen to be more concentrated at the painted/unpainted boundary with the different equipotential lines at right angles to current lines.

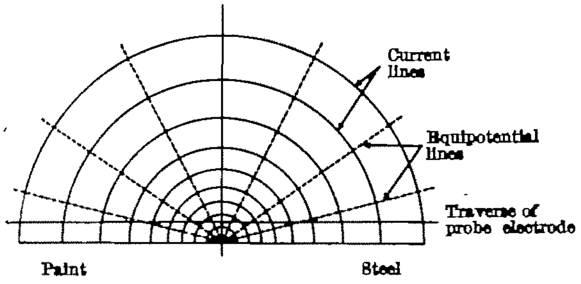

Fig. 1. Schematic representation of a contact couple formed by a half-painted mild steel specimen

The method consists essentially of scanning the surface of a specimen half-coated with a paint and immersed in a suitable electrolyte, noting the potentials recorded at regular distances (1 cm., 2 cm., 3 cm., etc.) from the boundary between the painted (cathodic) and the unpainted (anodic) areas. The scanning is effected by means of a probe calomel electrode with a potassium chloride/agar bridge with a fine capillary tip (0·60 mm. diam.). The reference (calomel) electrode is placed at a fixed distance from the probe electrode and does not traverse the surface of the specimen. The tip of the probe electrode is kept at a distance of approximately 1 mm. from the surface of the specimen. The potential values are recorded on a valve potentiometer.

The theoretical curves of potential against distance near the boundary between the anode and the cathode of a 'contact couple' are shown in Fig. 2; when the resistance of the electrolyte has an appreciably high value an S-shaped curve is normally to be expected[17].

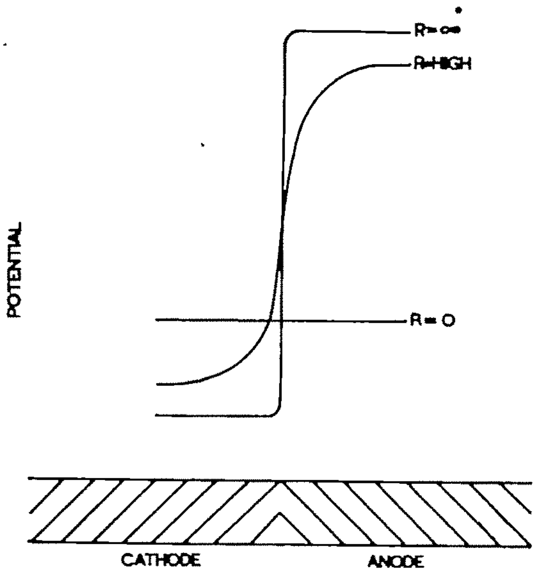

Fig. 2. Theoretical potential/distance curve for the area near the painted/unpainted boundary of a contact couple

Cathode, painted; anode, unpainted

After a number of experiments with various electrolytes, triacetin (glyceryl triacetate), containing approximately 3 per cent water, was chosen, because of its low electrical conductivity ($1 \cdot 1180 \times 10^{-8}$ mhos/cm. at 25° C.), stability, and non-reactivity with the paint film for the duration of the experiment.

A paint film may provide protection by: (1) resistance inhibition; (2) chemical inhibition. Both types of inhibition can be detected by a study of the S-shaped curve. Variations in the dimensions of the S curve may be correlated with different degrees of resistance inhibition, a curve that is small and compressed denoting better resistance inhibition than one that is large and elongated. Changes in the shape of the S curve, showing a decrease in the potential values over either the anodic or cathodic areas or both suggest chemical inhibition. A

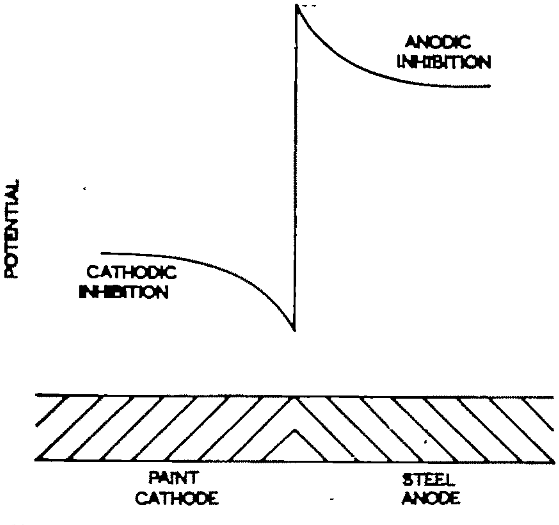

Fig. 3. Schematic representation of deviations from the ideal curve for potential/distance produced by anodic and cathodic inhibition

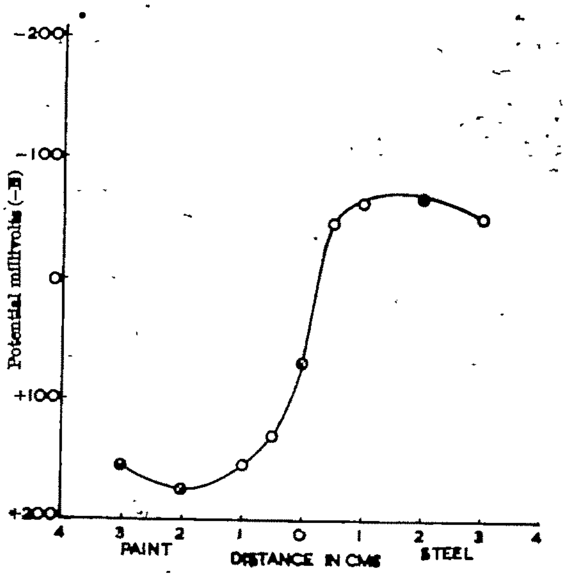

Fig. 4. Potential distribution between steel and red iron oxide

schematic representation of such a deviation from the ideal curve is shown in Fig. 3.

To illustrate the types of curves obtained with films containing red iron oxide or red lead in pale boiled linseed oil are shown in Figs. 4 and 5. Readings were taken every 15 min. until three consecutive sets of readings showed a constant value. A quick scanning was also carried out along two different paths over the panel to check the uniformity of the potential values. These values were then used to plot the potential/distance curves.

The curve obtained for the red iron oxide paint is smooth and S shaped, indicating that the contribution of this pigment specimen to protection against corrosion is likely to be one of improving the structural barrier effect of the paint medium to ingress of moisture as a corrosive agent. The curve obtained from the red lead paint, however, shows distortion over both anodic and cathodic areas, suggesting that this material, in addition to providing resistance inhibition, provides both anodic and cathodic chemical inhibition.

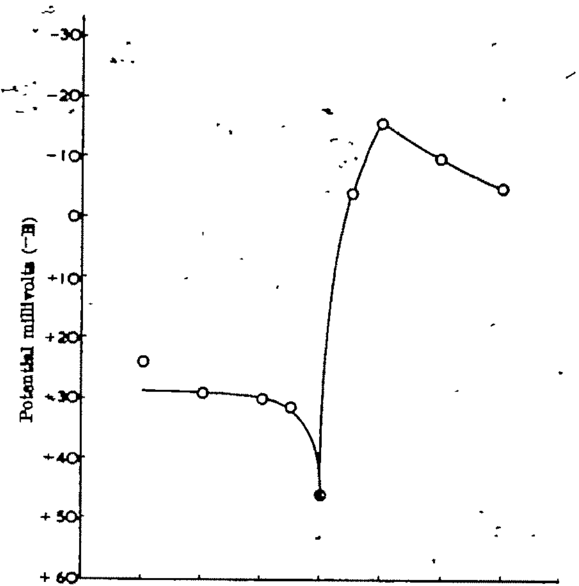

Fig. 5. Potential distribution between steel and red lead

Other priming paints have been studied and found to provide varying degrees of resistance inhibition and, in some cases, chemical inhibition.

SOME ASPECTS OF THE FIBRINOGEN-FIBRIN TRANSITION

By K. LAKI, JULES A. GLADNER
National Institute of Arthritis and Metabolic Diseases
AND
J. E. FOLK
National Institute of Dental Research, National Institutes of Health, Bethesda, Maryland

THE thrombin-catalysed conversion of fibrinogen to the insoluble gel-like polymer, fibrin clot, constitutes the final stage in the complex process of blood coagulation.

The observation that the thrombin-induced conversion of fibrinogen to fibrin clot is a two-phase process[1,2]: (1) an enzyme action modifying fibrinogen to fibrin, followed by (2) the aggregation of fibrin molecules, may be considered as the starting point in a systematic study of this last step in blood coagulation. Our present understanding of many of the chemical and physico-chemical reactions involved in this conversion is a result of the ingenuity and combined efforts of many investigators.

The Enzymatic Phase

The difference in isoelectric points[3] and titration curves of fibrinogen and fibrin[4] suggested that, in the enzymatic process, a small molecule (or molecules), bearing negative charges, was released from fibrinogen[5]. These suggestions were substantiated when non-protein nitrogen[6] and ninhydrin-reacting material[7] were found in the supernatant fluid of fibrin clots. Further studies revealed that the non-protein nitrogen, liberated during clotting, consisted primarily of two acidic peptides, afterwards designated peptides *A* and *B* (ref. 8). These findings indicated that thrombin was a protease. However, the exact nature of the bond or bonds acted upon by thrombin remained unknown. The finding that amino-terminal glutamic acid of fibrinogen is replaced by amino-terminal glycine in fibrin suggested that thrombin-catalysed hydrolysis occurred on the amino-side of specific glycine residues[9]. By the use of carboxypeptidase *B*, recently discovered in this laboratory[10,11], it was possible to demonstrate arginine as the carboxyl-terminal residue of both peptides *A* and *B*[12,13]. Since fibrinogen has no C-terminal arginine residues, it can be concluded that the peptides are bound to fibrinogen through their arginine end. This evidence directly substantiates the previous tentative conclusion that the bonds hydrolysed by thrombin to liberate these peptides are arginylglycine bonds.

The specificity of thrombin for ester or peptide bonds involving the carboxyl group of arginine has been demonstrated by the speed with which thrombin hydrolyses the synthetic substrate, tosyl-1-arginine methyl ester and its amide analogue, while scarcely attacking similar compounds of other amino-acids[14].

The proteolytic nature of thrombin was further demonstrated by the observation that the clotting as well as the esterase activity of thrombin becomes completely inhibited following treatment with di-*iso*propylphosphofluoridate[15,16]. This reagent is a powerful inhibitor of a number of hydrolytic enzymes.

Since thrombin inhibited by di*iso*propylphosphofluoridate can be restored to activity by chemical means, for example, by nucleophilic attack, it may be postulated that the localization of the *iso*propyl phosphate binding involves the active site. The *iso*propyl phosphate is bound so strongly to these enzymes that it survives mild acid hydrolysis. Employing di*iso*propylphosphofluoridate labelled with phosphorus-32 for the inhibition, the peptides containing the radioactive phosphorus following mild hydrolysis can easily be detected and isolated. We have isolated four such peptides of the inhibited thrombin[17].

The composition of these peptides is shown in Table 1. Since serine is the common amino-acid, it is reasonable to assume that the serine hydroxyl group is the site of the *iso*propyl phosphate binding. Furthermore, it was possible to show, by end-group and sequence analysis, that the sequence of amino-acids in the vicinity of this serine is gly.asp.ser.gly. This is the same sequence that was found at the active site of the proteolytic enzymes trypsin and chymotrypsin[18,19].

Table 1. RADIOACTIVE PHOSPHOPEPTIDES ISOLATED FROM THE SYSTEM DIISOPROPYLPHOSPHOFLUORIDATE-THROMBIN

Fraction of peptide	Amino-acid composition
2	(Asp, Ser, Gly)
4	(Asp, Ser)
5	(Ser, Gly)
7	(Asp, Ser, Gly)
8	(Asp, Ser, Gly, Glu, Ala)

These observations, which clearly class thrombin among the proteolytic enzymes, do not explain why the action of thrombin is limited to the hydrolysis of a few arginyl peptide bonds in fibrinogen. There must be many such bonds in this protein. Trypsin, for example, splits many arginyl bonds of several proteins, including fibrinogen, which are not susceptible to the action of thrombin (Mihalyi, E., personal communication). It is conceivable that the unique sequence of amino-acids around or in the vicinity of bonds susceptible to thrombin directs this 'limited proteolysis' in a manner similar to that postulated for the selective bond-cleavage which occurs during the tryptic activation of trypsinogen[20].

In order to explore this theory of 'limited proteolysis' as well as to obtain amino-terminal sequence data on fibrinogen, an amino-acid sequential analysis of peptides *A* and *B* was undertaken. For such investigations, peptides *A* and *B* were separated, isolated and purified by chromatography on an anionic cellulose exchanger. Combined sedimentation and diffusion results with the purified peptides indicated a molecular weight of 2,000 for peptide *A* and 2,400 for peptide *B*. The quantitative amino-acid analysis of these peptides gave minimum molecular weights of 1,890 and 2,460 for peptides *A* and *B*, respectively, in good agreement with the physical measurements[13,21].

Fig. 1. Summary of the proposed complete amino-acid sequence of peptide *A* and partial amino-acid sequence of peptide *B*

Fig. 1 shows the postulated amino-acid sequence of peptide *A* (ref. 22) and the partial amino-acid sequence of peptide *B*. (A sequence similar to that presented in this article with the exception of the position of one aspartic acid residue in peptide *A* has been reported recently in a short communication[23].) In peptide *A*, the free carboxyls of aspartic and glutamic acids are rather evenly distributed along the peptide chain and are separated from the C-terminal arginine by the gly$_3$.val sequence. The two adjacent proline residues can form a point at which the direction of the peptide chain may be reversed. It should be mentioned that the prolylproline sequence has been found in the melanophore-stimulating hormone from pig anterior pituitary gland[24]. This type of linkage (that is, between two cyclic amino-acids) has been suggested as a recurrent one in gelatin[25]. Although our present knowledge of the structure around the bonds of fibrinogen susceptible to thrombin is limited to the amino-acid sequence of peptide *A* and the partial sequence of peptide *B*, it is, nevertheless, tempting to speculate on the unique and narrow specificity of thrombin in its role of releasing these peptides from fibrinogen. There are in each peptide two proline residues as well as several dicarboxylic amino-acids—gly$_3$.val in the case of the *A* peptide, and val.gly.leu.gly.ala. in peptide *B*. The high density of negative charges, perhaps oriented in some specific manner relative to the remainder of the fibrinogen molecule, may contribute to the selective cleavage by thrombin. This type of structure has been postulated to be involved in the selective bond-splitting which occurs during the tryptic activation of trypsinogen[20]. Other residues or groups of residues in the peptide molecules may exert a further orienting effect, as suggested by the prolylproline sequence of peptide *A*. In line with this suggestion is the ability of thrombin to hydrolyse gelatin[26].

On the other hand, the structure of the peptides *per se* may play no part in the transition of fibrinogen to fibrin, other than that of masking hydrogen-bond donor or acceptor groups which are afterwards involved in polymerization[27] (see polymerization phase). Residues or groups of residues on the glycine side of the arginine glycine bonds which are attacked by thrombin may be altogether responsible in directing the specificity of this enzyme.

The enzymatic phase of the fibrinogen–fibrin transition may be summarized by the following reaction:

$$\text{fibrinogen} \overset{\text{thrombin}}{\rightleftarrows} \text{fibrin} + \begin{matrix}(\text{peptide } A)\\(\text{peptide } B)\end{matrix}$$

In the next step, fibrin molecules polymerize to form the clot, but the peptides *A* and *B* are left freely dispersed in the clot liquor. In co-operation with E. Leonard (National Heart Institute), we have observed the action of these peptides on the carotis muscle of rabbit. This effect is probably similar to the stimulating effect observed on frog heart by one of us[7]. With an isolated preparation of rabbit carotid artery strip, suspended in such a way that the muscle could be stimulated electrically and tension measured[28], it was found that 250 µgm./ml. of peptide *B* caused a slow rise in the tension exerted by the muscle fibres without electrical stimulation, and that in the presence of 80 µgm./ml. the tension developed in response to electrical stimulation was increased over control values. Although these results are based on experiments with only two preparations of peptide (on four strips of artery) and the specificity of the effects has not yet been adequately studied, it is tempting to speculate that in tissue trauma the cleavage of fibrinogen leads not only to clotting but also to local vasoconstriction through the release of the peptides. The local concentration of peptides *A* and *B*, assuming complete conversion of fibrinogen to fibrin, would be approximately 120 µgm./ml. Although the tissue concentration of peptide might well be less than the 80 µgm./ml. found to affect the contractility of the arterial strip, it is frequently observed that the sensitivity of smooth muscle in the large vessels is much less than that of the arterioles and pre-capillaries, and, therefore, a local constrictor action of the peptides *in vivo* remains a possibility.

The Polymerization Phase

Depending on conditions, *p*H, ionic strength, etc., the fibrin molecules formed in the enzymatic phase quickly aggregate to form a network-like structure, the fibrin clot. However, the aggregation is not completely random. For example, electron micrographs reveal interesting regularities in these clots[29]. In addition, various physicochemical measurements indicate that the fibrin molecules are held together in the clot by about ten hydrogen bonds[27]. Such a great number of bonds might be indicative of large areas of complementariness between these fibrin molecules, further suggesting that the molecules actually aggregate into a highly ordered network. The pattern and properties of this network are 'coded' into the fibrin molecules. In order to understand more fully the clotting process, this 'coded' pattern must be elucidated in terms of chemical bonds, bond patterns, and bond forces. For details, the reader is referred to a recent review by Scheraga and Laskowski[27].

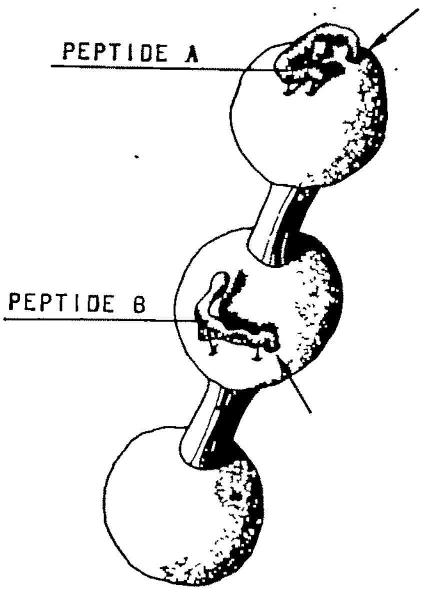

Fig. 2. Schematic representation of the fibrinogen molecules (ref. 33). The arrows indicate the location of the arg.gly. bonds, the site of thrombin action. The 'legs' on which the peptides stand indicate hydrogen bonds (ref. 27)

Recently the formation of four N-terminal glycine residues on fibrin, replacing the two N-terminal glutamic acid residues removed with peptides *A* in fibrinogen, was reported[30]. This is indicative of the rupture of four peptide bonds. This observation, coupled with the reported release of about 3 per cent of the fibrinogen nitrogen, can be satisfied by postulating the release of two each of the acidic peptides per 320,000 gm. of fibrinogen. One each of the peptides would be released from 160,000 gm. of fibrinogen, suggesting this value as the molecular weight for monomeric bovine fibrinogen.

Undoubtedly the removal of these peptides is a prerequisite for the subsequent polymerization of the fibrin molecules. These highly charged peptides could conceivably prevent the association of fibrinogen molecules (for example, by masking binding sites). It is of interest to speculate whether the removal of both these peptides is necessary for clotting, since it is possible to obtain a clot by snake venom enzyme with the removal of only peptide *A* from fibrinogen[31]. However, under conditions where only peptide *A* is released, the subsequent aggregation of fibrin molecules is almost exclusively end-to-end. Normally, both peptide *A* and *B* are released and the fibrin molecules aggregated end-to-end as well as side-by-side. It is thus possible to have essentially all fibrin molecules incorporated into a clot while the clotting process is still going on. Unless the end-point of the clotting is properly ascertained, one may conclude that the removal of only one of the peptides, peptide *A*, is necessary for normal clotting. The termination of the clotting process is clearly recognizable when the clotting is followed in a calorimeter; the cessation of heat evolution marks the end of clotting[32]. When the clot liquor is examined at this point, it is found that it contains both peptides *A* and *B*.

When the clotting is followed in a *p*H-stat, the uptake of base stops after the cleavage of two peptide bonds per 160,000 gm. (Mihalyi, E., personal communication). Again the clot liquor contains both the two peptides.

Since the release of peptide *A* favours end-to-end aggregation, one may conclude that peptide *A* is located at the end of the fibrinogen molecule and peptide *B* on the side of the molecule.

In electron microscopic examinations, the fibrinogen molecule appears to resemble a string of three beads with a total length of about 475 Å. (ref. 33). Accepting the localization of peptide *A* on the end, and *B* on the side, the fibrinogen molecule may be pictured as shown in Fig. 2. In this illustration the peptides are in their unfolded state. The lack of any helical structure in these peptides is inferred from optical rotation measurements we have made on the isolated peptides in purified form (unpublished results). There is also indication that these peptides have no helical structure when bound to the fibrinogen molecule, since no change in the optical rotation of fibrinogen is observed when the peptides are split off by thrombin[34].

The picture of fibrinogen–fibrin transformation is not complete without mentioning that the clot formed in normal plasma differs from that formed in the purified fibrinogen–thrombin system. While the clot formed in the purified system is soluble in 8 *M* urea, the normal plasma clot is not, indicating that in plasma some factor causes the formation of strong bonds between fibrin molecules. The existence of such a factor can easily be demonstrated[35].

The addition of calcium ions and serum to a purified fibrinogen–thrombin system results in a fibrin clot which is insoluble in 8 *M* urea. (This factor has been called *L-L* factor[36] or fibrin serum factor[37].) Recently this factor has been isolated and purified 8,000 fold[38] from human plasma and has been found to contain a number of easily oxidizable SH groups which are necessary for its activity. It is a protein with a molecular weight of about 1/2 million[38]. The mode of action of converting urea-soluble fibrin clot into urea-insoluble clot has not yet been fully elucidated, but the fact that very small amounts of the pure factor are enough to convert the clot into its insoluble form suggests that its action on fibrin is enzymatic. The factor apparently is manufactured in the blood-forming organs. In certain diseases, especially with serious disturbance in the metabolism of bone marrow, this factor is missing, only the defective urea-soluble clot being formed[39]. The problem of why bone marrow is involved in formation of blood clots is intriguing and remains to be investigated.

It is hoped that the few experiments discussed in this short review illustrate the extent to which the molecular aspects of the fibrinogen–fibrin conversion have been clarified by the efforts of scientists of varying disciplines. The realization is also emerging that the last phase of blood clotting is intimately inter-related to other physiological processes such as the normal functioning of the bone marrow and the contractility of the capillary bed.

POSSIBLE OCCURRENCE OF INTERFERENCE SYSTEMS IN VIRUS-INFECTED PLANTS

By A. D. THOMSON*

Agricultural Research Council Virus Research Unit, Huntingdon Road, Cambridge

INTERFERENCE between plant viruses was first demonstrated in plants infected with tobacco mosaic virus[1] and has since been demonstrated between serologically related strains of many plant viruses[2] and between some apparently unrelated viruses[3]. Although several theories have been proposed to explain interference[2], the most recent by Best[4], there is little evidence on the mechanisms involved. In the experiments described below interference was measured by the ability of an inoculum that does not produce local lesions (interfering strain) to affect the local lesions produced by

---

* Present address: Plant Diseases Division, Department of Scientific and Industrial Research, Christchurch, New Zealand.

another strain when the two are inoculated simultaneously to susceptible leaves. Inhibition of infections by lesion-forming strains in these conditions was first described by Sadasivan[5]. The present results suggest that sap from virus-infected plants contain, in addition to infective particles, another factor that inhibits infection.

Table 1 shows the extent to which unfractionated sap from leaves infected with tobacco mosaic virus, potato virus *X* and potato virus *Y* decreased the number of lesions produced by lesion-forming strains of these viruses. Reduction in lesion numbers was accompanied by reduction in recoverable infectious virus. In addition to fewer lesions being formed, those produced by the mixed inocula were smaller than those produced by the single strain.

Interference during simultaneous infection occurred with serologically related viruses (Table 1). Thus unfractionated extracts of 3 strains of tobacco mosaic virus inhibited the ribgrass and aucuba strains and extracts of 5 strains of virus *X* inhibited 3*XE*–1. Extracts of unrelated viruses did not inhibit tobacco mosaic virus or virus *X*. However, extracts from plants infected with severe etch virus, virus *Y* and tobacco mosaic virus inhibited infection by cabbage black ringspot virus (Table 1).

Virus preparations of apparent equal infectivity differed significantly in their ability to interfere with infection by lesion-forming strains. For example, with tobacco mosaic virus, interfering activity was greatly reduced by heating expressed sap at 55° or 60° C. for 10 minutes and by dialysing expressed sap against distilled water for 48 hours (Table 2). Loss of interfering activity also occurred during purification of the virus by precipitation with ammonium sulphate (Table 2) and after 5 cycles of high- and low-speed centrifugation.

In the case of virus *X*, freezing leaves before extracting sap resulted in elimination of interfering activity (Table 2) although this treatment did not reduce the interfering activity of tobacco mosaic virus.

Preparations of tobacco mosaic virus which showed little interference with infection did interfere with the size of lesions of the lesion-forming strain (Table 2). This suggests that two factors responsible for interference occur in unfractionated sap; one is more unstable than the virus and inhibits infection and another which is always associated with infectivity and inhibits virus synthesis or movement after infection. However, with all infectious preparations the interfering system would be formed after infection and the same factor may be responsible for both phenomena.

Table 1. INHIBITION OF LESION-FORMING BY NON-LESION-FORMING VIRUSES

Inoculum*		Mean lesions per half-leaf	
Interfering virus	Lesion-forming virus	Treated	Control
'Type' strain tobacco mosaic virus	Aucuba strain tobacco mosaic virus	9	108
'Type' strain tobacco mosaic virus	Cabbage black ring-spot virus	3	38
'Masked' strain tobacco mosaic virus	Ribgrass strain tobacco mosaic virus	16	135
AST4 strain potato virus *X*	3*XE*-1 strain potato virus *X*	20	92
TVNV strain potato virus *Y*	'Type' strain potato virus *Y*	19	64
'Type' strain potato virus *Y*	Cabbage black ring-spot virus	2	38
Severe etch virus	Cabbage black ring-spot virus	9	38

* Equal volumes interfering and lesion-forming viruses (treated) or healthy sap and lesion-forming viruses (control) rubbed on twelve tobacco (tobacco mosaic virus, virus *X* and cabbage black ringspot virus) or *Physalis floridana* (virus *Y*) half-leaves. Interfering preparations were unfractionated sap from infected leaves. The concentration of lesion-forming strains of tobacco mosaic virus was 0 02 mgm./ml. 3*XE*-1 was infective sap diluted 1/100, and virus *Y* and cabbage black ringspot virus were infective saps diluted 1/10.

Table 2. EFFECT OF TREATMENTS ON INTERFERING ACTIVITY OF TOBACCO MOSAIC VIRUS AND VIRUS *X*

Interfering preparation*	Mean No. lesions per half-leaf	
	Interfering prep. + lesion-forming strain	Healthy sap + lesion-forming strain
'Type' strain tobacco mosaic virus		
heated 60°/10 min.	84‡	109
unheated	16‡	128
dialysed	53‡	70
undialysed	4‡	70
precipitated once†	24‡	54
precipitated three times	60‡	54
unfractionated	14‡	58
inactivated by ultra-violet light	101	100
unirradiated	35‡	100
AST4 strain potato virus *X*		
from frozen leaves	45	40
from unfrozen leaves	4	64

* Equal volumes interfering preparation (expressed sap except where indicated otherwise) and lesion-forming strains (aucuba or 3*XE*-1) rubbed on twelve tobacco half-leaves with similarly treated sap from healthy plants on opposite halves.

† Virus precipitated with ammonium sulphate and concentration adjusted with distilled water to give preparations of infectivity equal to unfractionated virus.

‡ Lesions of lesion-forming strain restricted in size.

Except possibly for homologous antisera[6] and irradiated virus preparations[7] there is little evidence for specificity in the action of plant virus inhibitors. The present phenomenon appears to differ from that described by Bawden and Kleczkowski[7], since preparations of tobacco mosaic virus which inhibited infection were not inhibitory when inactivated by ultra-violet light (Table 2). Virus protein prepared by fission of tobacco mosaic virus with alkali is also an inhibitor of infection[8], but there is no evidence that it is specific. Expressed sap from leaves infected with tobacco mosaic virus was centrifuged at 36,000 r.p.m. for 60 min. in rotor 40 of the Spinco model *L* ultracentrifuge. Interfering activity was not present in the supernatant fluid. This suggests that certain anomalous proteins associated with virus infection are not involved with interference. Density-gradient centrifugation of tobacco mosaic virus and virus *X* in sucrose showed that infectivity and interfering activity occurred in the same zone in the gradient. If interference systems occur, then these appear to be in some way associated with virus particles. Virus multiplication also results in the appearance of other products in extracts from virus-infected plants, and of particular interest here is a virus-inactivating system present in plants infected with Rothamsted tobacco necrosis virus and tobacco ringspot virus[8]. This inactivating system seems to differ from interference; for example, the inactivating system does not occur in tobacco plants infected with tobacco mosaic virus[9].

HISTOCHEMICAL LOCALIZATION OF HUMAN, TERM PLACENTAL 17β-ŒSTRADIOL DEHYDROGENASES: IMPLICATIONS FOR THE TRANSHYDROGENASE REACTION

By DR. DONALD A. KELLOGG and DR. GEORGE G. GLENNER

National Institutes of Health, Bethesda, Maryland

THREE 17β-œstradiol-sensitive enzyme systems have been described in human, term placental homogenates: a diphosphopyridine nucleotide (DPN)-linked dehydrogenase, a triphosphopyridine nucleotide (TPN)-linked dehydrogenase, and a TPNH–DPN transhydrogenase[1-4]. Although previous work suggested that these reactions were mediated by a single enzyme which, because of its dual nucleotide specificity, could function as a transhydrogenase[2-4], Hagerman and Villee recently isolated separate and distinct protein fractions for each system[5]. The presence of di- and tri-phosphopyridine nucleotide as co-factors in these reactions suggested that histochemical experiments might give further insight into the problem. If only one protein exists, or if the function of the two dehydrogenases is to mediate transhydrogenation, one would expect similar cellular localization of the two dehydrogenases. On the other hand, dissimilar histochemical localization of the two nucleotide-linked dehydrogenases would be consistent with the existence of more than one protein system catalysing the dehydrogenation of 17β-œstradiol. The validity of demonstrating histochemically a specific nucleotide-linked dehydrogenase by means of tetrazolium salts had been discussed by Cascarano and Zweifach[6]. Using histochemical techniques, Pearson and Grose demonstrated a 17β-œstradiol diphosphopyridine nucleotide-linked dehydrogenase in rat liver and small intestine[7]; and Wattenberg studied a diphosphopyridine nucleotide-linked 3β-ol steroid dehydrogenase in rat ovary, adrenal cortex, testis, and liver and human corpus luteum, adrenal cortex, and the syncytiotrophoblast of term placenta[8]. In these experiments, no attempt was made to demonstrate a triphosphopyridine nucleotide-linked reaction; however, Wattenberg suggested that the presence of a 3β-ol steroid dehydrogenase implied the existence of a steroid synthesizing mechanism.

The present histochemical observations show that the two 17β-œstradiol dehydrogenase reactions of human, term placenta have characteristically different cellular localizations.

Ten term placentas were frozen within 30 min. of delivery; fresh frozen sections, 10μ thick, were cut on a freezing microtome, mounted on slides, and immediately incubated in appropriate media for 1–3 hr. at 37° C. Other specimens were fixed for 4 hr. in neutral, 10 per cent formalin, washed, and carried through identical sectioning and incubation procedures. The incubation medium for demonstration of dehydrogenase activity consisted of 2 moles of pH 7·4 *tris* buffer, 2 μmoles of steroid substrate, 50 μmoles of oxidized nucleotide, 50 mgm. of crystalline bovine albumin, and 10 mgm. of nitro-blue tetrazolium salt in a final volume of 20 ml. The addition of 1 μmole of Mg^{++} or 0·2 μmole of Zn^{++} to the medium did not alter the staining characteristics. For histochemical localization of tri- or di-phosphopyridine nucleotide diaphorase, 50 μmoles of reduced nucleotide replaced steroid substrate and oxidized nucleotide in the incubating medium.

Tri- and di-phosphopyridine nucleotide diaphorase were demonstrated in cells of the trophoblast, stroma and decidua. There was no difference in the distribution or intensity of the two diaphorase reactions. Staining in the presence of 17β-œstradiol and diphosphopyridine nucleotide was most prominent in cells of the trophoblast and decidua and less intense in the stroma (Fig. 1*a*). Incubation with 17β-œstradiol and triphosphopyridine nucleotide produced intense staining of the perivascular stroma; but there was no detectable reaction in the cells of the trophoblast or decidua following 1 hr. incubation (Fig. 1*b*). Although a 3-hr. incubation in the presence of 17β-œstradiol and triphosphopyridine nucleotide produced a minimal reaction in the trophoblast, the staining differences described above were accentuated.

Either oxidized nucleotide incubated with 17α-œstradiol, stilbœstrol or œstrone produced no staining. Both dehydrogenase reactions were inhibited by 50 μmoles of mercuric chloride in the incubating medium. Raising the *p*H to 8·6 did not appreciably affect the reaction although lowering it to 6·4 lessened the intensity of staining. These data are in general agreement with known biochemical findings[2-4].

Because of the recognized limitations of the histochemical technique, it cannot be stated unequivocally that the differences demonstrated here are not due to such factors as differences in binding of tetrazolium salt, the existence of a diffusable enzyme, differences in reaction-rates with the two nucleotides, interaction of steroid with diaphorase or oxidase, or coupling of enzyme to diaphorase.

To investigate the possibility that the marked staining of the trophoblast and decidua in the diphosphopyridine nucleotide-linked reaction was due to preferential binding of tetrazolium salt, placental slices were incubated in the usual medium containing all constituents except nucleotide and steroid substrate. Following the washing of these sections and the reduction of the tetrazolium salt with 0·1 per cent ammonium polysulphide solution[9], no preferential decidual or trophoblastic binding was noted.

To determine if enzyme diffusion occurred, placental slices were overlaid on inactivated rat kidney slices and incubated in appropriate media. Moderate staining of the kidney in the presence of 17β-œstradiol and diphosphopyridine nucleotide was obtained, but there was no detectable staining of the kidney in the presence of 17β-œstradiol and triphosphopyridine

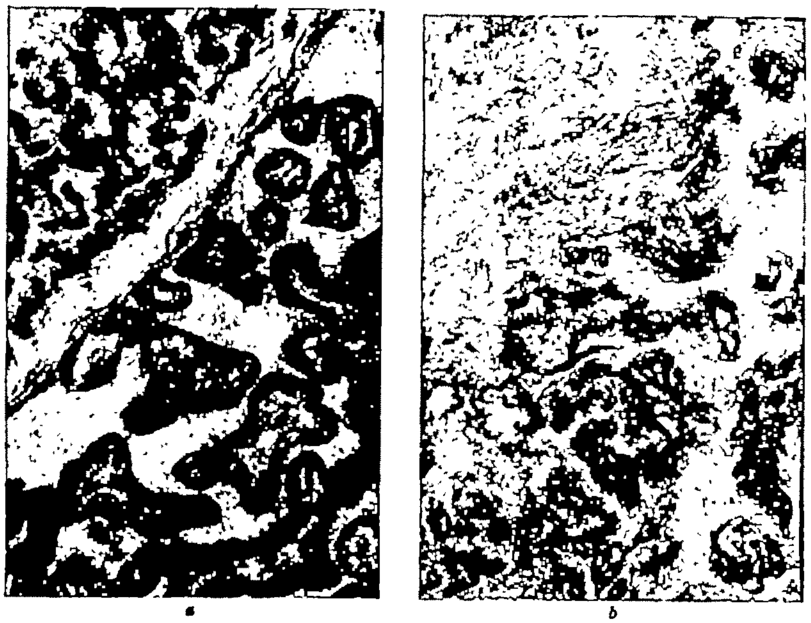

Fig. 1. *a*, Localization of 17β-œstradiol diphosphopyridine nucleotide-linked dehydrogenase. *b*, Localization of 17β-œstradiol triphosphopyridine nucleotide-linked dehydrogenase

nucleotide following 1 hr. incubation. Formalin fixation for 4 hr. did not alter these phenomena. Either reduced nucleotide incubated without steroid substrate in overlay experiments produced no staining of the inactivated rat kidney. Incubation of placental sections in buffer alone for 15–30 min. followed by transfer to a medium containing substrate and oxidized nucleotide revealed a decrease rather than an increase in trophoblastic and decidual staining.

Although these differences in staining of the overlaid kidney may be partly or wholly explained by the fact that placental homogenates reduce triphosphopyridine nucleotide in the presence of excess 17β-œstradiol approximately one-half as rapidly as diphosphopyridine nucleotide[4,5], the total lack of triphosphopyridine nucleotide-linked reaction in the inactivated rat kidney militates against it. Further, this cannot explain the characteristically different staining patterns observed in the placental slices with the two nucleotides and the fact that these differences are accentuated by prolonged incubation.

The possibility that 17β-œstradiol is affecting the diaphorase differentially or inhibiting reduced diphosphopyridine nucleotide oxidase, as shown biochemically by Yielding and Tomkins[10], and thereby diverting electrons to diaphorase, was examined by incubating placental slices with reduced di- or triphosphopyridine nucleotide and steroid. No significant differences resulted when compared with identical incubations without steroid.

That these results are explained by the existence of one enzyme coupled predominantly to triphosphopyridine nucleotide diaphorase in the stromal cell and only to diphosphopyridine nucleotide diaphorase in the trophoblastic cell appears unlikely in view of the intense reaction in the trophoblastic cell in the presence of reduced triphosphopyridine nucleotide.

In placental homogenates the diphosphopyridine nucleotide-linked reaction can be inhibited by small quantities of triphosphopyridine nucleotide[6]. Attempts were made to demonstrate this histochemically by pre-incubation of a placental slice for 5–15 min. in a medium containing triphosphopyridine nucleotide followed by incubation with 17β-œstradiol and diphosphopyridine nucleotide for 1 hr. There was no significant difference between the resulting staining pattern when compared with controls preincubated in buffer and albumin. The same findings resulted when slices were preincubated in diphosphopyridine nucleotide and transferred to a medium containing 17β-œstradiol and triphosphopyridine nucleotide for 1 hr. Incubation in a medium containing 17β-œstradiol and both oxidized nucleotides resulted in a summation of the staining patterns which resulted upon incubation with either nucleotide individually.

The observations in this histochemical system for the two dehydrogenase reactions strongly suggest that at least two distinct 17β-œstradiol-sensitive enzymes are being demonstrated. If the function of these two enzymes is to perform transhydrogenation, or if there is only one enzyme which because of its dual nucleotide specificity can perform transhydrogenation, one might expect the staining reactions to be similar. In these experiments such was found to be the case only in the stromal cell. The apparent absence of significant 17β-œstradiol triphosphopyridine nucleotide-linked dehydrogenase activity in the cells of the trophoblast and decidua where the 17β-œstradiol diphosphopyridine nucleotide-linked dehydrogenase activity is most prominent makes it unlikely that the two dehydrogenases function together in these cells principally as mediators of TPNH–DPN transhydrogenation. It is suggested that the different distributions of the two dehydrogenase reactions in these two cell-types reflects a different qualitative function for 17β-œstradiol in each cell. It is noteworthy that the diphosphopyridine nucleotide-linked reaction resides in the syncytiotrophoblast, the site of a diphosphopyridine nucleotide-linked 3β-ol steroid dehydrogenase presumably associated with a steroid synthesizing apparatus, and predominantly in those tissues directly associated with implantation, that is, trophoblast and decidua—tissues which have no significant triphosphopyridine nucleotide-linked activity.

We wish to express our thanks to the physicians of the Obstetrical Unit of the National Naval Medical Center for their generous assistance, and to Dr. Roy Hertz for his helpful advice and criticism.

CRYSTALLOGRAPHY

Mimetic Twinning in Urea–Ammonium Bromide

DURING an investigation of the crystal structure of the 1 : 1 complex formed by urea and ammonium bromide it was found that certain of the crystals obtained from solution exhibited orthorhombic symmetry whereas the remainder appeared to belong to the lower monoclinic system. Examination of these under the polarizing microscope did not reveal any obvious macrotwinning.

Structure determination afterwards revealed the true symmetry to be monoclinic and the pseudo-symmetry shown by some of the crystals appears to be a result of twinning by crystallites of small dimensions.

The pseudo-orthorhombic cell may be satisfactorily accounted for on the grounds of equal numbers of crystallites twinned as a result of a 180° rotation about the *c* axis as shown below. The symmetry of the monoclinic cell projection is *p*2 and the resulting symmetry of the orthorhombic cell *cmm* (shown in dotted outline).

In order for it to be possible for an orthorhombic cell of this symmetry to result from this type of twinning, the geometrical relation $a \cos \beta = \frac{c}{4}$ must hold within the monoclinic cell. This is satisfied by the complex with $a = 8{\cdot}9$ Å., $c = 7{\cdot}1$ Å. and $\beta = 102°$. (The relationship mentioned above is similar to that which results in twinning according to the Carlsbad law as evidenced in felspar when $a \cos \beta = \frac{c}{2}$.)

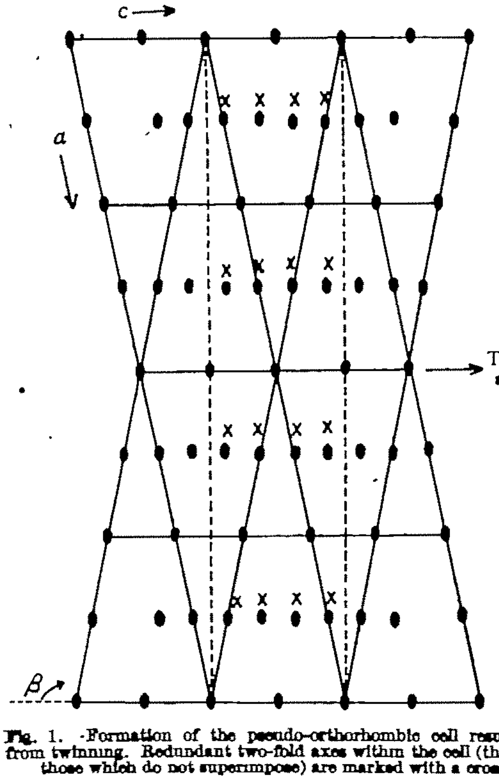

Fig. 1. Formation of the pseudo-orthorhombic cell resulting from twinning. Redundant two-fold axes within the cell (that is, those which do not superimpose) are marked with a cross

A further feature resulting from this twinning is that only half the urea molecules and bromide ions are directly superimposed in projection along with *b* axis, and consequently the Fourier map for this projection of the pseudo-orthorhombic cell shows a set of peaks for these having only half the expected electron density.

Further work on the structure is in progress and full details will be published later.

PHYSICS

Pure Rotational Association of Ozone in the Region 125–500 Microns

PURE rotation spectra of gaseous ozone have been recorded in the laboratory for the wave-length range 125–500μ. This extends the region observed by Danti and Lord (125–200μ) to longer wave-lengths, but has a useful overlap with their results[1]. It also covers part of the observed far infra-red solar spectrum where some unidentified features were attributed to absorption by ozone in the upper atmosphere[2].

Ozone was made by passing oxygen through a glass apparatus with an annular region in which there was a silent discharge. A mixture of oxygen and ozone was condensed in a trap surrounded by liquid nitrogen and, by slowly warming up the trap, the oxygen was removed by fractional distillation, leaving liquid ozone. This was then evaporated into an absorption cell which was part of the interferometer arrangement shown in Fig. 1. In this the whole optical path between the source and the detector can be evacuated to a pressure of less than 10^{-3} mm. mercury, and a trap cooled externally with liquid nitrogen further reduces the amount of water vapour to the point where its absorption is negligible. The glass absorption cell was 10 cm. in length and was fitted with crystal quartz windows 2 mm. thick. These were sealed with silicone rubber 'O' rings, and silicone grease was used in stopcocks and joints connecting the cell to the rest of the gas-handling equipment. With this arrangement the stability of the sample was such that the amount, measured by the total absorption, was not less than half the initial amount after 25 min., which was the time taken to complete one run. Interferograms were recorded, and spectra derived from them by Fourier transformation on a digital computer. The methods used for this, as well as a full description of the interferometer, will be given in later publications. Brief descriptions have already been published[3].

Fig. 2 shows typical results from a number of spectra recorded. Each curve was obtained by finding the ratio of ordinates of a pair of spectra, one taken with gas in the cell and one with the cell evacuated. For comparison are also shown the centres of gravity of the *Q* branches of ozone as calculated by Gora[4] (full lines) from microwave observations, and the positions and strengths of the strongest lines of H_2O as given by Benedict in a private communication (dotted lines). No relationship between the intensities of ozone and water lines is implied in the scale of the figure.

It will be seen that the absorption of *Q* branches observed at the positions indicated is well marked, but elsewhere the reproducible features in the spectra largely correspond to the positions of water lines. These are not present in the spectra taken with the cell evacuated and must be caused by water in the ozone sample itself. Since this has been evaporated from a trap at a temperature of about 150° K., it seems certain that the water must have resulted from the reaction of ozone with something in the cell. The only likely material would be the silicone rubber or silicone grease.

The spectral resolution, here defined as the width at half-intensity of a spectral window which is approximately gaussian, is about 0·8 cm.$^{-1}$ for the spectra shown. A number of runs have also been made with the higher resolution of 0·3 cm.$^{-1}$ but have not so far given any new information. The scale of intensity can only be given roughly since there are two sources of uncertainty. The first is the decay of the sample during the run; the second is that the scale depends on the assumption that the continuous background absorption is negligible at some selected point chosen in taking the ratios of the spectra. The values of absorption at the 46-cm.$^{-1}$ minima in the spectra *A*, *B* and *C* were, respectively, 34, 29 and 40 per cent.

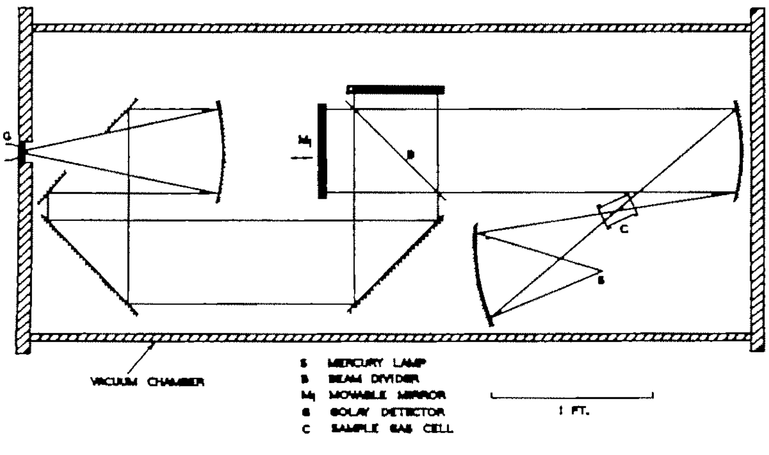

Fig. 1

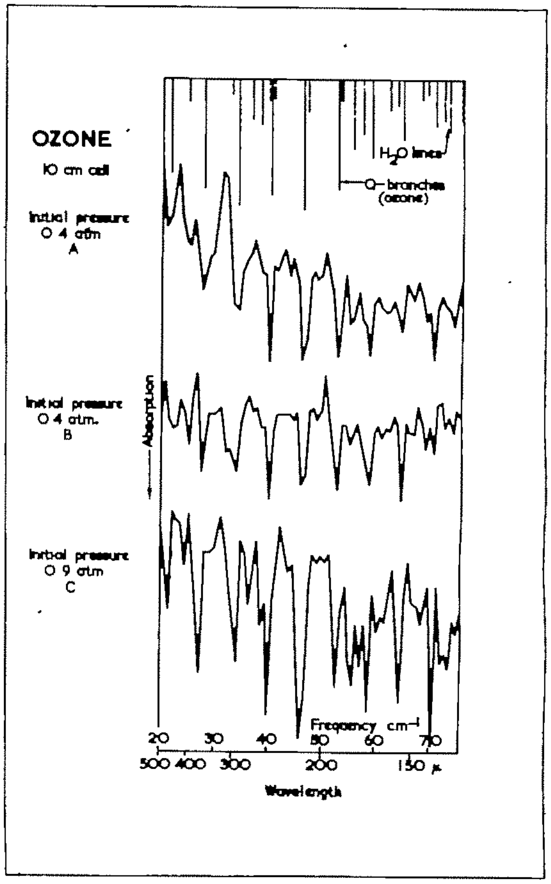

Fig. 2

These results extend the range in wave-length where there is agreement between the positions of observed minima and Gora's prediction of the centres of gravity of *Q* branches of ozone. In the region where the present results overlap with those of Danti and Lord, there is agreement and their conclusions are supported. In particular, the claim is also made here that much valuable data on the structure of molecules can easily be obtained from far infra-red spectra that can be derived only by considerable labour from microwave observations. The reason is that although the spectral resolution obtainable in the far infra-red is orders of magnitude smaller than in the microwave region, the range that can be studied is very much greater. In this way the two techniques may be complementary.

The confirmation that *Q* branches are observed near 22 cm.$^{-1}$ and 28 cm.$^{-1}$ in the laboratory spectra makes plausible the suggestion that unidentified features in the solar spectrum could be attributed to ozone in the upper atmosphere. There still appear to be problems, however, in reconciling the intensities of the laboratory and solar spectra, and further work will be required on both.

Equations for determining Diffusion Coefficients in Liquid Systems by the Diaphragm Cell Technique

THE diaphragm-cell technique, first introduced by Northrop and Anson[1], has been widely used as an experimental method of utilizing Fick's first law to obtain diffusion coefficients in liquids. The procedure is a simple one whereby diffusion takes place through a porous diaphragm separating two cells in which the respective liquid concentrations, initially different to provide a driving force or potential for diffusion, are maintained uniform. It is made clear by Gordon[2] in his classical review of the experimental and theoretical basis of the method that certain simplifying assumptions must be made in its utilization. These assumptions include constant solution volumes and constant fluxes throughout the porous diaphragm at any given moment. In measurements involving dilute solutions of electrolytes, the errors introduced by these assumptions have been analysed[2,3] and found to be unimportant. In the present work the magnitude of the error introduced by the second assumption was assessed for typical diaphragm diffusion cell conditions (including consideration of a binary non-electrolyte system). Dropping this assumption, the resulting system of differential equations was solved by a numerical method. Comparison of the times required to produce a given concentration change with and without the above assumption showed a difference of not more than 0·02 per cent. The first assumption of constant solution volumes, however, may introduce significant error whenever the system is one that displays volume change on mixing. The importance of accurate liquid diffusion coefficients has led us to replace, with a more general expression, the simple logarithmic equation, given by Gordon[2], that applies admittedly only if there is no change in volume on mixing:

$$\ln\frac{(c'-c'')_f}{(c'-c'')_i} = -\left[\left(\frac{1}{v'}+\frac{1}{v''}\right)\frac{A}{l}\right]D\,.\,t = -\beta\,.\,D\,.\,t \qquad (1)$$

where c' and c'' are concentrations, and v' and v'' are volumes of the half-cells, f and i refer to final and initial states respectively, A and l are the effective path area and length respectively, and β is the 'cell factor'.

The general approach proposed utilizes the expressions for diffusion coefficients obtained by de Groot[4] by using the methods of the thermodynamics of irreversible processes with the mass flux given in terms of chemical potential as a driving force. The assumption that the system is close enough to equilibrium for the flux to be proportional to the first power of the chemical potential gradient is made. Bird[5] has tabulated the various types of notation used for binary systems. The following fundamental equation may then be taken (at constant temperature and pressure):

$$n_A = -\rho\,.\,D_{AB}'\,.\left(\frac{\partial\omega_A}{\partial x}\right) + \omega_A\,.\,(n_A+n_B) \qquad (2)$$

$$\text{with } D_{AB}' = D_{AB}\,.\left(\frac{\partial\ln a_A}{\partial\ln\omega_A}\right) \qquad (3)$$

where n_A and n_B are the fluxes of components A and B in gm. cm.$^{-2}$ sec.$^{-1}$, with respect to the apparatus as a frame of reference; ρ is mass density (overall concentration) in gm. cm.$^{-3}$; ω_A is concentration of A as mass fraction; a_A is thermodynamic activity of component A; x is positional co-ordinate for unidirectional diffusion; D_{AB} is diffusion coefficient; and D_{AB}' is modified diffusion coefficient incorporating the activity correction. In this equation the fluxes are considered with respect to stationary axes but the diffusion coefficient is the so-called barycentric diffusion coefficient, that is, taken with respect to the mass average velocity. Comparable equations result for other terms of reference.

For the 'steady state' assumption involved in this application of irreversible thermodynamics, we propose substituting the concept of 'space constant material transport across the diaphragm'. Using this premise and with rigorous application of the above equation to the diaphragm-cell experiment, the following equation has been derived for the integral diffusion coefficient, $\overline{D}_{AB}'$:

$$\overline{D}_{AB}' = \frac{\ln R + I}{\beta\,.\,t}\,(\overline{\omega}_A{}^*\,.\,\overline{\gamma}_{BA} + \overline{\omega}_B{}^*)\left(\frac{2}{1+\overline{K}}\right) \qquad (4)$$

$$\text{where } R = \frac{(\rho_A'-\rho_A'')_i}{(\rho_A'-\rho_A'')_f} = \frac{(\Delta\rho_A)_i}{(\Delta\rho_A)_f};$$

$$I = \int_{v_i''}^{v_f''}\frac{\rho_A''}{\Delta\rho_A\,.\,V''}\,.\,\mathrm{d}V'';$$

$$\gamma_{BA} = \frac{\overline{n}_B}{\overline{n}_A};$$

$$K = \frac{\rho''\,.\,\omega_A' - \rho'\,.\,\omega_A''}{\Delta\rho_A};$$

$\rho = \rho_A + \rho_B$ is mass density (overall concentration) in gm. cm.$^{-3}$; ρ_A is concentration of A in gm. cm.$^{-3}$; v is volume (cm.^{3}); ω_A is concentration of A as mass fraction; n_A is flux of component A in gm. cm.$^{-2}$ sec.$^{-1}$; t is diffusion time, sec.; superscript $'$ is closed half-cell; superscript $''$ is open half-cell; $-$ is mean of initial and final values; $*$ is mean of the values at the bottom and the top of the diaphragm; subscript i is initial value at time $t = 0$; subscript f is final value at time t; and subscripts A,B are components A,B ($A \neq B$).

The integral diffusion coefficient $\overline{D}_{AB}'$ is related to the true differential value D_{AB}' by the following rigorous equation:

$$\overline{D}_{AB}' = \frac{(\ln R + I)\,(\overline{\omega}_A{}^*\,.\,\overline{\gamma}_{BA} + \overline{\omega}_B{}^*)\left(\dfrac{2}{1+\overline{K}}\right)}{\displaystyle\int_0^t\frac{\rho_A''}{F(\omega_A',\omega_A'')}\,.\,\mathrm{d}\ln v'' - \int_0^t\frac{\mathrm{d}\Delta\rho_A}{F(\omega_A',\omega_A'')}} \qquad (5)$$

where
$$F(\omega_A' \cdot \omega_A'') = \int_{\omega_A''}^{\omega_A'} \frac{\rho \cdot D_{AB}'}{(\omega_A \cdot \gamma_{BA} + \omega_B)}\, d\omega_A \qquad (6)$$

For an excellent approximation:

$$\bar{D}_{AB}' = \frac{(\bar{\omega}_A^* \cdot \bar{\gamma}_{BA} + \bar{\omega}_B^*)}{\bar{\rho}^*} \cdot \frac{1}{\bar{\omega}_A' - \bar{\omega}_A''} \cdot \int_{\bar{\omega}_A''}^{\bar{\omega}_A'} \frac{\rho \cdot D_{AB}'}{(\omega_A \cdot \gamma_{BA} + \omega_B)} \cdot d\omega_A \qquad (7)$$

It mey be noted that all the terms can be evaluated from overall density-composition data, to give a diffusion coefficient which has the same value regardless of whether the concentrations of component A or of component B are used, and regardless of whether the half-cell containing the more- or the less-concentrated solution is open.

It can be shown when ρ is constant, or ρ is $a + b\rho_A$ (that is, no volume change on mixing), that equation (3) reduces to equation (1), and equation (7) becomes:

$$\bar{D}_{AB}' = \frac{1}{\bar{c}_A' - \bar{c}_A''} \cdot \int_{\bar{c}_A''}^{\bar{c}_A'} D_{AB}' \cdot dc_A \qquad (8)$$

Extensive precision measurements on the ethanol–water system have been made. The calculated diffusion coefficients, based on these equations, and the complete derivation of these equations will be reported later.

The use of the equations presented here will now allow the use of large concentration differences in diaphragm cell experiments, and permits the calculation of accurate differential coefficients, D_{AB}', from a series of values of $\bar{D}_{AB}'$ the integral coefficients. The precision of the experimental determination of the latter is, of course, enhanced greatly by utilizing conditions of large concentration differences. The conversion of the values of D_{AB}' to the corresponding D_{AB} values can be done whenever the activity is known as a function of composition.

CHEMISTRY

Energies of Activation for Self-diffusion of Alkali Metal Ions in Analcite

THE self-diffusion coefficients and energies of activation for migration of alkali metal cations in analcite have recently been measured[1]. We now find that when these energies are plotted against α_1, the polarizabilities of the cations, the linear graph shown in Fig. 1 is obtained. This line can be represented by the equation:

$$E = 10{\cdot}5 + 6{\cdot}6 \times \alpha_1 \times 10^{24} \qquad (1)$$

where E is expressed in kcal./gm. ion and α_1 in cm.^{3}/ion.

Diffusion of a cation along a channel, the walls of which are, as in analcite, lined with negatively charged oxygens, must involve coulombic, polarization, dispersion and repulsion energies. The variation in coulombic energy as the ions diffused was calculated in ref. 1 for an idealized system approximating to that existing in analcite. This periodic variation of coulombic energy for a univalent cation diffusing along the channel resulted in a contribution, ΔE_c, of approximately 10 kcal./gm. ion to the overall energy of activation. This coulombic energy is independent of the polarizability of the cation, thus accounting for the term in equation 1 which is independent of polarizability, although the good agreement between experimental and calculated values is no doubt fortuitous considering the simplifications made in the calculations referred to[1].

The polarization energy of a cation of polarizability α_1 in a field of strength, F, is, to a first approximation:

$$E_P = -\tfrac{1}{2}\alpha_1 F^2 \qquad (2)$$

and therefore the activation energy for diffusion of the cation due to polarization would be:

$$\Delta E_P = -\tfrac{1}{2}\alpha_1 (F_T^2 - F_B^2) \qquad (3)$$

where F_B and F_T are the fields existing at an equilibrium cation site and at the point in the channel corresponding to the top of the energy barrier respectively. Thus $\Delta E_P = \alpha_1 B$, where B is a constant.

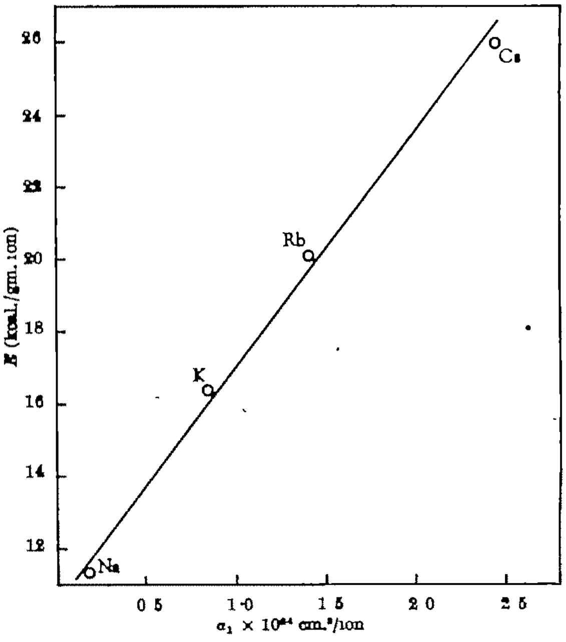

Fig. 1. Relationship between energy of activation for self-diffusion of alkali metal cations in analcite and the polarizability of the cations

The dispersion repulsion energy can be evaluated from the relation:

$$E_{D+R} = -6Nmc^2 \frac{\alpha_1\alpha_2}{\alpha_1\chi/_1 + \alpha_2/\chi_2} \sum_{r's} \left(\frac{1}{r^6} - \frac{r_e^6}{2r^{12}}\right) \quad (4)$$

where α_1, α_2 and χ_1, χ_2 are the polarizabilities and diamagnetic susceptibilities of the cation and of oxygen respectively, m is the mass of the electron, N is the Avogadro number and c the velocity of light; r denotes the distance between the oxygen and cation centres, and r_e is the equilibrium oxygen : cation separation. α_1/χ_1 is approximately constant for the four cations considered here, and thus equation 4 can be written:

$$E_{D+R} \simeq -\alpha_1 \times \text{constant} \sum_{r's} \left(\frac{1}{r^6} - \frac{r_e^6}{2r^{12}}\right) \quad (5)$$

and, as in the case of the polarization energy:

$$\Delta E_{D+R} \simeq -\alpha_1 \times \text{constant} \sum_{r's} \left\{ \left(\frac{1}{r_1^6} - \frac{r_e^6}{2r_1^{12}}\right)_T - \left(\frac{1}{r_2^6} - \frac{r_e^6}{2r_2^{12}}\right)_B \right\} \quad (6)$$

where r_1's and r_2's are the distances between cation centres and the centres of framework oxygens when the cations are on equilibrium sites and at the top of the energy barriers respectively. Accordingly, all r_1's and r_2's are constant for all ions so long as the equilibrium positions and those of the tops of the energy barriers are the same. The r_e's will differ among the ions, so the terms in $1/r^6$ are constant for all ions but not those in $1/r^{12}$. If the latter are small, we may write:

$$\Delta E_{D+R} = \alpha_1 C \quad (7)$$

where C is a coefficient which does not vary greatly among the ions. The total energy of activation, E, can then be represented by an equation of the same form as equation 1, since, according to the above treatment:

$$E = \Delta E_C + \Delta E_P + \Delta E_{D+R} = 10 + (B + C)\alpha_1 \quad (8)$$

In general, polarizability is proportional to ionic volume for similar ions of the same valence, and a linear relation was observed also between E and the volumes of the cations.

Differential Thermal Analysis of Some Transition Metal Ethylenediamine Tetraacetic Acid Chelates

One of the least-studied aspects of co-ordination chemistry is the thermal properties of metal complexes with organic chelating agents. With such easily available instruments as the automatic recording thermobalance and differential thermal analysis apparatus, physical parameters such as minimum and maximum temperature limits for dehydration and pyrolysis reactions, rate-studies of thermal decomposition reactions[1], and detection of intermediate compounds formed during pyrolysis are easily attainable. Such information is needed in order to understand more fully the nature of certain types of thermal rearrangements and in synthesis work.

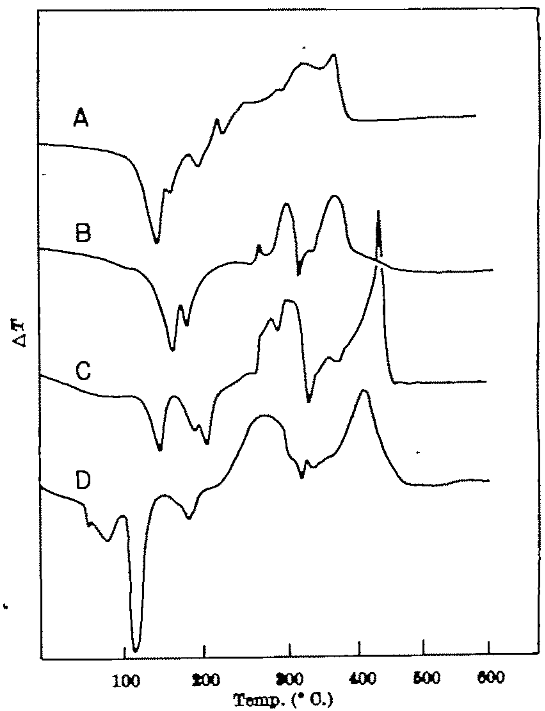

Fig. 1. Differential thermal analysis curves for metal ethylenediamine tetraacetic acid compounds. *A*, $Na_2CuEDTA\cdot3H_2O$; *B*, $Na_2ZnEDTA$ $3H_2O$; *C*, $Na_2CoEDTA$ $4H_2O$; *D*, $Na_2MnEDTA$ $5-6H_2O$

Although the thermal stability of a number of complexes is known[2], little information can be obtained concerning the thermal decomposition of transition metal ethylenediamine tetraacetic acid (EDTA) chelates. Previous work has been limited to the determination of the optimum drying temperatures for the salts, $Na_2EDTA\cdot2H_2O$ (refs. 3–5) and $Na_2CaEDTA\cdot2-3H_2O$ (ref. 5). It was found that the former could be converted to the anhydrous compound by heating to 120° C., but that temperatures above 150° C. resulted in decomposition of the salt. Similarly, the latter complex was dehydrated in the 37–180° C. temperature-range, with decomposition beginning at 337° C. In order to study further the thermal decomposition of the ethylenediamine tetraacetic acid metal complexes, the compounds $Na_2M\text{EDTA}\cdot n\text{H}_2O$, where M is cobalt(II), copper(II), manganese(II), and zinc(II), were examined by differential thermal analysis.

The apparatus for differential thermal analysis consisted of a furnace, similar in design to that previously described[6], and a microvolt strip-chart recorder and furnace temperature controller[7]. Sample sizes ranged in weight from 125 to 140 mgm. with calcined alumina being used as the reference material. A heating-rate of 8·0 deg. C. per min. was employed with a chart speed of 6 in. per hr.

The metal ethylenediamine tetraacetic acid complexes were obtained from the Geigy Chemical Co. (we are indebted to Dr. W. H. Zussman for providing these compounds), and were recrystallized from water–alcohol mixtures before pyrolysis. Thermobalance analysis[8] established the amount of hydrate water present in the complex and also the composition of the residual thermal decomposition product.

The resulting thermograms of the differential thermal analyses are given in Fig. 1. All the complexes gave pronounced endothermic (downward direction) peaks below 200° C. which were due to the evolution of hydrate-bound water. Immediately following the dehydration reactions, a series of exothermic (upward direction) peaks were observed which were due to the pyrolysis of the anhydrous salts. The pyrolysis of the complexes appears to proceed stepwise, as evidenced by the number of peaks observed. Since the reactions were carried out in air, the decomposition products were probably gaseous carbon dioxide, nitrogen, water and ammonia, and residues consisting of mixtures of sodium carbonate and metal oxide.

The thermal stability of the hydrates, as shown by the endothermic peak minima, was: manganese (80°) 110° < copper, 140° < cobalt, 145° < zinc, 160° C. Some idea as to the heat of hydration can be obtained by comparing the areas under the dehydration peaks. All the complexes were 3-hydrates except manganese, which appeared to have the composition, 5–6 hydrate. Naturally, with the larger number of molecules of water of hydration on the manganese it would have the largest peak area; however, a rough comparison can be made with the other complexes.

Some difficulty was experienced in obtaining reproducible exothermic peaks beyond 250° C. This was due to the tendency of the complexes to swell to voluminous proportions in the sample chamber during the pyrolysis, which resulted in pockets of air and erratic thermal conductivity of the samples. Hence, the differential response of the thermocouple was affected by this behaviour.

It is planned to continue this work with other metal complexes of ethylenediamine tetraacetic acid.

A New Technique for following Rapid Rates of Crystallization

TECHNIQUES for measuring rates of crystallization have been the subject of recent reviews[1,2]. Most of the methods described are not applicable to fast rates. A microscope-ciné camera technique[3] can be used when the species crystallizes in visibly discernible forms; but interpretation of results is sometimes complicated by impingement of boundaries between the crystalline entities. A method independent of the texture of the crystallizing species but requiring birefringence in the crystallized specimen has been developed in these laboratories. This consists, essentially, of following the increase in depolarization of plane-polarized light by the crystallizing specimen. Birefringence and crystallinity do not occur concurrently under all conditions of crystallization[4], but it is believed that when crystallization takes place from a melt under no external stress, measurement of rate of depolarization of light by the crystallizing sample parallels the development of crystallinity.

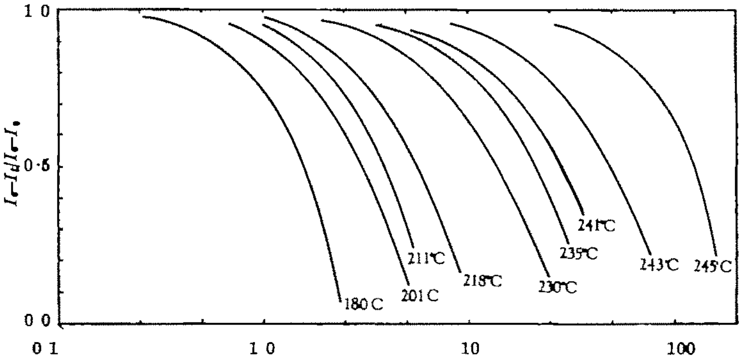

Fig. 1

Sections of dry polyhexamethylene adipamide (nylon 66) were melted in silicone oil between coverslips and then transferred rapidly to a thermostatted hot-stage mounted between crossed nicols on a microscope. Depolarization of the plane-polarized light was followed by a photomultiplier connected to a cathode-ray oscilloscope and recorded by a camera fitted to the cathode-ray oscillograph. A time-base superimposed on the photographic trace facilitated calibration and measurement. The instrument was calibrated using standardized neutral density optical filters; over the range of outputs studied, photomultiplier response was stable and linear. After the polymer melt specimen was transferred to the hot-stage a finite induction time, τ, elapsed during which no depolarization occurred. With the onset of crystallization, the photomultiplier output increased exponentially to a maximum rate and then the rate decreased as a pseudo-equilibrium crystallinity was attained. Characteristic sigmoidal isotherms were obtained for each crystallizing temperature. Both the induction period and the crystallization time decreased with decrease in crystallizing temperature in the range 170–255° C., but a minimum is expected in the region 160–170° C. where nylon 66 is believed to crystallize most rapidly.

Normalized plots of $\frac{I_e - I_t}{I_e - I_o}$ against t for each isotherm are superimposable and fit the Avrami equation[5]:

$$\ln\left(\frac{I_e - I_t}{I_e - I_o}\right) = -kt^n$$

where I_o = initial photomultiplier output; I_e = final photomultiplier output; I_t = photomultiplier output after time t(sec.); k = constant; n is a constant characteristic of the type of nucleation.

This technique does not provide information on the relative contributions of the nucleation and growth processes involved, but corresponding information may be obtained from spherulitic growth studies at low degrees of supercooling[1–3].

Fig. 1 shows normalized plots of $\frac{I_e - I_t}{I_c - I_e}$ versus t for various crystallization temperatures. The majority of these isotherms are coincident on displacement of the time axis, in agreement with specific volume/time curves, and are typical of rate measurements[4].

Fig. 2 shows plots of $\log\left(\frac{1}{t_{\frac{1}{2}}}\right)$ against $\frac{1}{T°\text{K.}}$ for the light transmission method superimposed on $\log G$ versus $\frac{1}{T°\text{K.}}$ for spherulitic growth-rate measurements[3] ($t_{\frac{1}{2}}$ = time when $\frac{I_c - I_t}{I_c - I_0} = 0{\cdot}5$; G = growth-rate in μ/min.). Results indicate that the apparent activation energies involved in both cases are similar, and this substantiates the similarity between the measurements.

This technique has been applied to other homopolymers under conditions where no visible spherulitic crystallization was apparent. It has also been shown to be an accurate method for melting-point determinations.

A more detailed account of the apparatus and analysis of results will be published later.

Use of Azo Dyestuffs for the Polarographic Determination of the Lanthanides

The polarographic behaviour of some 2,2′-dihydroxy azo dyes in the presence of the lanthanides has recently been a subject of study in this laboratory. The lanthanides were found to form coloured chelates in alkaline solution with eriochrome violet *B* (5-sulpho-2-hydroxy benzene-azo-2-naphthol, *C.I.* No. 169), eriochrome black *PV* (5-sulpho-2-hydroxy benzene-azo-1,5-dihydroxy naphthalene, *C.I.* No. 170) and mordant blue 31 (5-sulpho-2-hydroxy benzene-azo-1,8-dihydroxy naphthalene 3,6-disulphonic acid, *C.I.* No. 16675). These dyes all exhibit well-defined single polarographic reduction waves. In ammonia, diethanolamine and piperidine buffers, the lanthanides cause a decrease in height of the dye step, and a second wave appears at a more negative potential. The height of the second wave is proportional to the concentration of lanthanide.

Eriochrome violet *B* has previously been used for the polarographic determination of aluminium[1,2], thorium and zirconium[3]. This dye was also found the most suitable of those investigated for the present purpose, and was studied in detail using d.c. and a.c. pen polarography and linear-sweep cathode-ray polarography. The lanthanides combine with eriochrome violet *B* in a 1 : 2 ratio, with apparent stability constants in the range 10^9 for neodymium to 10^{12} for ytterbium at *p*H 9. The azo group is believed to be involved in the co-ordination, this accounting for the difference in reduction potential of the free dye and dye-lanthanide complex. In an ammonia buffer of *p*H 9, the difference in the half-wave potentials of the free dye and complex was found to increase with increasing atomic number of the lanthanide, being 45 mV. for lanthanum, and 234 mV. for lutetium. This permits simultaneous determination of the lighter and heavier lanthanides in admixture. In piperidine buffer (*p*H 11) the half-wave potentials of the complexes are all very similar, being separated from the dye wave by about 180 mV.

The development of an analytical method necessitated a fundamental study of the polarographic behaviour of 2,2′-dihydroxy azo dyes at the dropping-mercury electrode. The behaviour of both the dye and the lanthanide complex is greatly influenced by adsorption of one or more forms at the mercury interface. These adsorption phenomena were investigated in some detail by a.c. polarography; tensammetric waves being observed for the dye, the reduced dye, and the dye-lanthanide complex.

A complete account of this work will be published elsewhere in due course.

Structure of $AgSCN.P(n\text{-}C_3H_7)_3$

Complexes of silver iodide with *n*-alkyl trisubstituted phosphines are tetrahedrally co-ordinated[1]. Complexes with trico-ordinated silver can be prepared with substituted alkyl–aryl phosphines[2]. Electronic effects due to alkyl substitution cannot be neglected, as factors which could influence the change in co-ordination[3]; however, their importance must not be over-emphasized[3]. In fact, silver(I) very easily changes its co-ordination according to the nature of co-ordinating groups, and the factors which affect the changes of stereochemistry are not at all clear[4].

Earlier work[5] on complexes of silver thiocyanate and silver iodide with tri*cyclo*hexylphosphine has shown that silver is tri-co-ordinated in AgSCN.2PCy_3 (the situation being more complicated for the silver iodide derivative). X-ray preliminary results have shown that the silver atoms are not bonded by —SCN— bridges. In agreement with the structure in the solid state, the compound was found to be monomeric in freezing benzene.

On the other hand, it is known that silver thiocyanate has a polymeric structure, the silver atoms being bound to nitrogen and sulphur atoms by two covalent bonds. The non-linearity of this co-ordination is a very interesting feature of the structure[6].

The crystal structure of $AgSCN.NH_4SCN$ is built up by silver thiocyanate molecules, and silver forms only one 'true' covalent Ag—S bond (2·47 Å.). However, the nature of three further 'long' Ag—S bonds (2·63, 2·65, 2·74 Å.)[7] must also be taken into consideration before any definite conclusions on the real stereochemistry of silver in this compound can be drawn.

With these results in mind we found it of interest to investigate the compounds with general formula AgSCN.PR_3, extending our earlier study on AgSCN.2PCy_3 to a larger number of aliphatic phosphines.

The following previously unknown compounds were prepared by reaction of silver thiocyanate dissolved in ammonium thiocyanate water solution, and the corresponding phosphines: AgSCN.PEt_3 (m.p. 121° C.), AgSCN.PPr_3^n (m.p. 66° C.), AgSCN.PPr_3^i (m.p. 99° C.). The compound AgI.PPr_3^i (m.p. 205° C.) was also prepared in a similar way. These compounds are all non-electrolytes ($\Lambda_M \approx 10^{-2}$ in 10^{-3} molar nitrobenzene solution). The degree of association of AgSCN.PPr_3^i, determined cryoscopically in benzene, is 2·0, whereas that of the AgSCN.PPr_3^n is between 2·2 and 3·0. A dimeric structure (in solution) seems likely for the former compound, and interaction between the dimeric molecules is probably very weak also in the solid state. The degree of association of AgI.PPr_3^i is 3·5 in benzene. This compound clearly belongs to the class of four-covalent complexes of the type $[AgI.PR_3]_4$ (R = *n*-alkyl)[1].

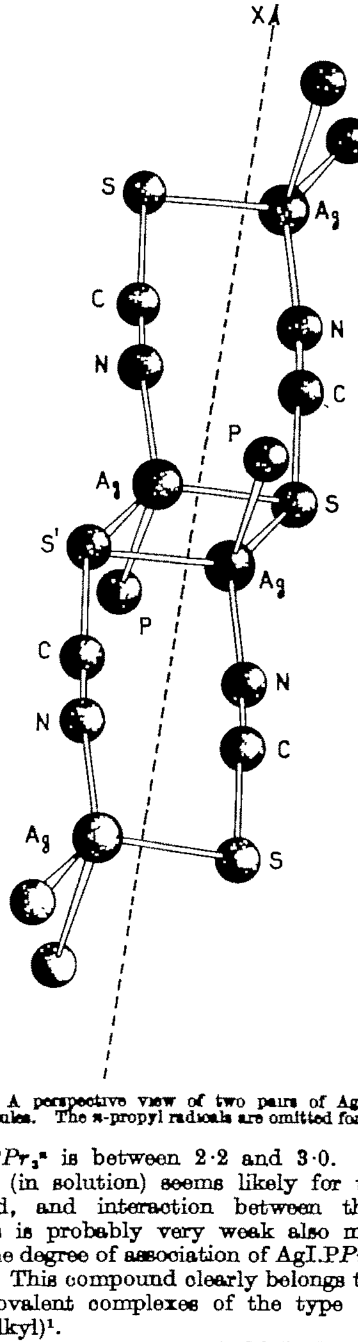

Fig. 1. A perspective view of two pairs of AgSCN.PPr_3^n molecules. The *n*-propyl radicals are omitted for clarity

The crystal structure of AgSCN.PPr_3^n has been determined from two-dimensional X-ray data. There is still some question about the exact positions of the light atoms but the general picture of the structure is well established. Determination of the parameters by means of precession photographs gave the following data: AgSCN.PPr_3^n. *M*, 326·2. Monoclinic. *a* =

Table 1. Bond-Lengths and -Angles

Bond	*d* (Å.)	Angle	θ (deg.)
Ag—S	2·79	P—Ag—N	137
Ag—S'	2·74	S—Ag—N	104
Ag—P	2·52	S'—Ag—P	111
		S—Ag—P	107
Ag—N	1·96	S'—Ag—N	108
N—C	1·28	S—Ag—S'	94
		Ag—S'—C	98
C—S	1·76	Ag—S—C	103

$6{\cdot}32 \pm 0{\cdot}02$, $b = 14 \pm 0{\cdot}04$, $c = 18{\cdot}24 \pm 0{\cdot}05$ Å. $\beta = 114 \pm 20'$. Absent spectra, $h0l$ when l is odd, $0k0$ when k is odd. Space group $C^5_{2h} - P2_1/c$. Four molecules per unit cell. Volume of unit cell = 1482 Å. (ref. 3), d, calc. 1·45, measured 1·41.

The structure has been resolved by means of the usual two-dimensional methods. Intensities were estimated photometrically from several series of Weissenberg photographs by using copper K_α radiation. At the present stage of refinement the reliability factors are $R = 0{\cdot}15$ on the projection (100) and $R = 0{\cdot}13$ on the projection on (010). Bond-lengths and -angles are given in Table 1. The mean probable error of the atomic co-ordinates, calculated with Luzzati's method[8], is 0·06 Å. Owing to the differences in weight of the atoms it is reasonable to assume that the error in the bond-lengths of the heavy atoms is 0·04 Å., and of the light atoms is 0·15 Å.

The molecular configuration is shown in Fig. 1. The silver atoms are linked by two —SCN— groups forming 8-membered quasi-planar rings. This type of bridging of two metal atoms by two —SCN— groups has been found previously in two complexes of cadmium[9,10], and in the platinum compound $[Pt_2(SCN)_2Cl_2(PPr_3^n)_2]$ (ref. 11). The planar units are linked by Ag—S bonds, forming an endless chain arranged along the X-axis as shown in Fig. 1. Alternatively the structural arrangement can be described as zigzag . . . —Ag—SCN—Ag—SCN— . . . polymeric chains bound in couples by Ag—S cross-linking. The steric arrangement of the ligands about the silver atom is that of a very distorted tetrahedron. The Ag—P bond is of normal length (2·52 Å.), but the Ag—S bond-length is considerably greater (2·74–2·79 Å.) than the distance of 2·43 Å. reported in silver thiocyanate[6].

There are two possible causes of the ionic character of the Ag—S bonds, and their relative importance cannot at present be decided. The first is the possible conjugation of the π electrons of the —SCN— group with the σ electrons of the Ag—S bond. The second is the electro-neutrality requirement on the silver atom. The former effect is probably more important in $[Pt_2(SCN)_2Cl_2(PPr_3^n)_2]$, where the length of the Pt—S bonds (2·44 Å.) is greater than expected for a Pt—SCN bond (2·27–2·30 Å.)[11]. In the present case the ionic character of the Ag—S bond is presumably attributable to the effect of charge distribution. In this respect the apparent absence of double-bonding character of the Ag—P bond becomes significant, indicating that negative charge has not been transferred from filled d orbitals of the silver to empty orbitals of the phosphorus atom. The different situation of the —SCN— group is consistent with the shift of the —CN— stretching frequency from 2,150 cm.⁻¹ observed for AgSCN (ref. 12) to 2,090 cm.⁻¹ found in the present case[13].

A full account of this work will be given after further refinement of the structure has been completed.

BIOCHEMISTRY

Synthesis and Biological Properties of L-Arginyl-L-Prolyl-L-Prolyl-Glycyl-L-Phenylalanyl-L-Seryl-L-Phenylalanyl-L-Arginine, an Octapeptide related to Bradykinin

A structure has recently been proposed[1] for bradykinin, a plasma peptide obtained from or blood. The isolation, purification and amino-acid composition of this substance were reported earlier by the same workers[2]. The apparent importance of this peptide and its small size have prompted us to undertake its synthesis and a more detailed study of its biological action. Our first preparation of this octapeptide showed little bradykinin-like activity in several biological tests. While our synthesis and biological work were therefore being rechecked, workers[3,4] in two other laboratories reported the synthesis of this peptide and its lack of expected activity on the guinea pig's ileum. In the present communication we describe its synthesis and biological examination, which confirm and extend this recently published work.

The synthetic approach adopted made extensive use of the p-nitrophenyl ester method of peptide synthesis[5], which has recently proved itself in a synthesis of oxytocin[6]. N-Carbobenzoxy-L-phenylalanine-p-nitrophenyl ester was condensed with nitro-L-arginine methyl ester, giving the dipeptide in 95 per cent yield, m.p. 154–155° (reported[7] m.p. 160–161°).

N-Carbobenzoxy-L-phenylalanyl-nitro-L-arginine methyl ester was treated with hydrogen bromide in acetic acid, giving the dipeptide ester hydrobromide, m.p. 169–171°. Found: C, 41·55; H, 5·42; N, 18·00. Calc. for $C_{16}H_{25}N_6O_5Br$: C, 41·47; H, 5·44; N, 18·14. The dipeptide was allowed to react with N-CBZ-L-seryl azide, which yielded N-CBZ-L-Ser-L-Phe-NO_2-L-Arg methyl ester as colourless needles, m.p. 180–181°, $[\alpha]_D^{24} - 30{\cdot}2°$ (c 2, methanol). Found: C, 54·14; H, 5·88; N, 16·31. Calc. for $C_{27}H_{35}N_7O_9$: C, 53·90; H, 5·86; N, 16·29. After removal of the carbobenzoxy group with hydrogen bromide in acetic acid, the tripeptide ester was condensed with N-CBZ-L-phenylalanine-p-nitrophenyl ester, giving an 87 per cent yield of the crystalline tetrapeptide, m.p. 159–161°, $[\alpha]_D^{24} - 23{\cdot}8°$ (c 2, methanol). Found: C, 57·53; H, 6·17; N, 14·75. Calc. for $C_{36}H_{44}N_8O_{10}$: C, 57·84; H, 5·92; N, 14·96. Treatment with hydrogen bromide in acetic acid removed the amine protection and the resulting tetrapeptide ester and N-CBZ-glycyl-p-nitrophenyl ester gave small colourless needles of N-CBZ-Gly-L-Phe-L-Ser-L-Phe-NO_2-L-Arg methyl ester in 83 per cent yield, m.p. 180–181° (a different sample melted at 165–166° with identical rotation and analysis), $[\alpha]^{24}_{D}$ – 13·7° (*c* 2, dimethylformamide). Found: C, 56·62; H, 5·97; N, 15·20. Calc. for $C_{38}H_{47}N_9O_{11}$: C, 56·63; H, 5·88; N, 15·64. Removal of the carbobenzoxy group was again accomplished with hydrogen bromide in acetic acid, the hydrogen bromide removed from the peptide with '*IRA*-410 (OH^-)' resin and subsequent reaction with N-CBZ-L-proline-*p*-nitrophenyl ester gave N-CBZ-L-Pro-Gly-L-Phe-L-Ser-L-Phe-NO_2-L-Arg methyl ester as microneedles, m.p. 175–176°, $[\alpha]^{24}_{D}$ – 31° (*c* 1, dimethylformamide). Found: C, 57·31; H, 6·27; N, 15·11. Calc. for $C_{43}H_{54}N_{10}O_{12}$: C, 57·18; H, 6·02; N, 15·51. The heptapeptide N-CBZ-L-Pro-L-Pro-Gly-L-Phe-L-Ser-L-Phe-NO_2-L-Arg methyl ester was prepared in the same manner as the hexapeptide and it was found to be rather low melting (125–130°), which was attributed to the two proline residues. The protected heptapeptide was obtained as colourless rosettes from methanol, $[\alpha]^{24}_{D}$ – 35·2° (*c* 1, dimethylformamide). Found: C, 57·31; H, 6·16; N, 15·10. Calc. for $C_{48}H_{61}N_{11}O_{13}$: C, 57·63; H, 6·14; N, 15·40. Reaction of the decarbobenzoxylated heptapeptide (hydrogen bromide in acetic) with the *p*-nitrophenyl ester of tricarbobenzoxy-L-arginine[8] (m.p. 126–127°). Found: C, 62·02; H, 5·20; N, 10·25. Calc. for $C_{36}H_{35}N_5O_{10}$: C, 61·97; H, 5·06; N, 10·04) gave the fully protected octapeptide, m.p. 130–135°, $[\alpha]^{24}_{D}$ – 32·4° (*c* 1, dimethylformamide). Found: C, 58·72; H, 6·08; N, 14·47. Calc. for $C_{70}H_{85}N_{15}O_{18}$: C, 59·02; H, 6·16; N, 14·75. Hydrolysis of the methyl ester and one carbobenzoxy group with 1 *N* sodium hydroxide in methanol followed by hydrogenation in acetic acid/methanol using palladium black catalyst gave the triacetate salt of L-Arg-L-Pro-L-Pro-Gly-L-Phe-L-Ser-L-Phe-L-Arg. Found: C, 50·86; H, 7·31; N, 16·91. Calc. for $C_{51}H_{78}N_{14}O_{16}.3H_2O$: C, 51·16; H, 7·07; N, 16·38. Titration with perchloric acid in acetic acid gave an equivalent weight of 401, which is in agreement with a molecular weight of 1,197. Paper chromatography of the octapeptide using two different solvent systems (*iso*propyl alcohol : ammonia : water; *tert*-butyl alcohol : acetic acid : water) gave R_F values of 0·26 and 0·43 respectively with no impurities being indicated (Sakaguchi and bromphenol blue; the ninhydrin test was negative).

The synthetic octapeptide was compared with partially purified bradykinin, prepared by the action of crystalline trypsin on heated beef globulin, standardized against pure bradykinin obtained from similar starting materials[9]. The synthetic peptide (133 μgm./ml.) did not cause contraction of the guinea pig's ileum *in vitro*; but in its presence bradykinin was slightly potentiated. Like bradykinin[9], the peptide relaxed rat's duodenum *in vitro*, but its potency was very roughly 1/6,000 that of pure bradykinin. Unlike bradykinin[10], the peptide (4–16 mgm./kgm.) did not cause broncho-constriction in guinea pigs *in vivo*, but it slightly potentiated this effect of bradykinin. Like bradykinin[11], intradermal doses of the peptide increased the permeability of the skin capillaries of guinea pigs blued with pontamine blue 6*BX*. Its potency was about 1/1,000 that of pure bradykinin.

When given in high doses to four biological preparations, L-Arg-L-Pro-L-Pro-Gly-L-Phe-L-Ser-L-Phe-L-Arg. failed to show two biological properties of bradykinin, and showed another two very weakly.

We wish to thank Dr. D. F. Elliott, Dr. G. P. Lewis and Dr. E. W. Horton for a specimen of pure bradykinin and Dr. I. M. Lockhart and Mr. W. A. Jones for supplies of partially purified bradykinin.

Homotransplant Antigens: Preparation of Active Cellular Fractions

WE have reported recently a method for the measurement of the antigenicity of whole splenic cells using highly inbred strains of mice in a homotransplant system[1]. Using this method of assay, we have tested fractions of mouse splenic cells for antigenic activity. Below are described the preparation and properties of tissue fractions active as antigens in a homotransplant system. Other methods of preparation of antigenic fractions from tissues have been described by Billingham, Brent and Medawar[2], by Berrian and Brent[3], by Hašková and Hrubešová[4], by Castermans and Oth[5], and Lejeune-Ledant and Albert[6].

A plunger-type homogenizer, similar to one described by Philpot and Stanier, was used[7]. It consists of accurately drawn heavy-walled glass tubing 10 in. long and 1 in. internal diameter (Fischer and Porter Co., Hatboro, Penn.) and two stainless steel plungers with clearances of 0·0015 and 0·0005 in. A centrifuge, maintained in a cold room at 3–5° C., and capable of 20,000*g* acceleration, was employed for sedimentation. A 'Vir-tis' (Mod. 23) homogenizer was used for high-speed blending. *C57/Bl* 6 male mice, weighing 20 gm. or more, were the recipients and *C3H* or *A/He* male mice weighing 20 gm. or more, were the donors (obtained from the Roscoe B. Jackson Memorial Laboratories, Bar Harbor, Maine).

All preparative steps were carried out at 3–5° C. Mice of donor strains (*C3H* or *A/He*) were killed by cervical luxation. The spleens were excised, chilled in cold 0·15 *M* saline and processed without delay. Groups of 3 or 4 spleens, placed upon a piece of 40-mesh stainless steel screen which was supported on a funnel, were sliced longitudinally, and the pulps were pressed gently through the screen by means of a flat spatula. A fine stream of cold balanced salt solution was directed intermittently on to the tissue in order to wash cells from the screen and the funnel. Calcium ion concentration was kept at 0·0015 *M*; in its absence agglutination occurred. The suspended cells were drawn gently back and forth through a pipette with a wide orifice, and were diluted to a volume of 10–20 ml. per spleen (cell concentrations of 20 to 10 × 10⁶ cells/ml.). After standing about 10 min., the cell suspension was separated from the larger clumps by decanting into a beaker. Aliquots (1 ml.) of the cell suspension were removed after thorough mixing and diluted with 3 per cent acetic acid, and cell counts were performed in a hæmacytometer.

The decanted cell suspension was then sedimented at 4,000*g* for 10 min. The supernatant solution was discarded. The packed cells were resuspended gently, using the plunger with the 0·0015-in. clearance; the suspending medium (2–5 ml. per spleen) was buffered saline (0·13 *M* sodium chloride and 0·01 *M* phosphate, '0·15 *M*', *p*H 7·2–7·3; calcium was absent). Some cell agglutination usually occurred. After sedimentation at 4,000*g* for 10 min. the supernate was decanted and examined microscopically for cells. No cells were found, and the supernate was sedimented at 20,000*g* for 30 min.

The sediment recovered after 4,000*g* centrifugation was recycled four times, using the above sequence of steps with the following modifications: homogenization was effected (rather than resuspension) by vigorous use of the plunger with 0·0005-in. clearance (but production of foam was avoided), and the suspending media (2–5 ml. per spleen), each used twice in succession, were buffered saline diluted with one and four volumes of water ('0·075 *M*' and '0·03 *M*' saline respectively). As above, all supernates were reserved for subsequent 20,000*g* centrifugation.

The sediment obtained after the last homogenization in 0·03 *M* buffered saline was swirled gently in 0·015 *M* saline (about 1 ml. per spleen) in order to lower the ionic strength of the residual saline solution in the sediment without gelling the nucleoprotein. The suspension was then sedimented at 4,000*g*, and the sediment was dispersed by high-speed blending in distilled water (2–3 ml. per spleen). An initial increase of viscosity was evident in about 30 sec., followed by a rapid decrease. After about 2 min. blending, the solution had a low viscosity. The sediment obtained after centrifugation at 4,000*g* was discarded. This supernate, like the others, was opalescent and was centrifuged at 20,000*g*.

Centrifugation of the supernates at 20,000*g* for 30 min. resulted in recovery of a small amount of greenish-tan sediment. Although the supernatant solutions were clear, protein could be precipitated from all by lowering the *p*H to 5 with 0·1 *N* acetic acid.

The greenish-tan sediments recovered after 20,000*g* were resuspended in isotonic saline, either separately or admixed, and these were assayed for antigenic activity. The volumes of these suspensions were adjusted so that 1 ml. contained the greenish-tan sediment extracted from 50 × 10⁶ cells (hereafter referred to as the 'test sediment').

In our test system the test sediment was injected intraperitoneally in 2 ml. of 0·15 *M* saline. Four days later a 1-cm.² full thickness test skin graft, freed of all panniculus, was placed on the intact panniculus carnosus of the recipient strain. The test grafts were excised on the sixth day and were examined histologically. The percentages of surviving epithelium were scored as 0, 10, 25, 50, 75, 90 and 100 per cent, and these values were converted to integers 0–6 respectively for statistical convenience[1].

Table 1. COMPARISON OF ANTIGENIC ACTIVITY OF FRACTIONATED MOUSE SPLEEN CELLS DETERMINED BY SCORES OF TEST SKIN HOMOGRAFTS

Test sediment from	Score*
0·15 *M* fraction	3, 3, 2, 1, 0, 0, 0†
0·075 *M* fraction	4, 3, 3, 3, 2, 1, 1†
0·03 *M* fraction	4, 4, 3, 3, 3, 3, 2†
Water dispersed	5, 5, 5, 4, 4, 4, 4
Control	6, 5, 5, 5, 5, 4, 4

* Maximum antigenicity is indicated by the figure 0.
† Statistically distinguishable from control on $P = 0·05$ level or better (Student '*t*' test).

The antigenic activity of the test sediments from one experiment are shown in Table 1. When considerable antigenic activity was recovered from the 0·15 *M* and 0·075 *M* saline fractions, antigenic activity in the 0·03 *M* saline fraction and the water-dispersed fraction was either feeble or absent. This distribution of antigenicity among the fractions appears to reflect the vigour with which the homogenizer was used to disrupt cells. In other experiments, when homogenization was less vigorous, there was a more even distribution of antigenicity among the fractions. However, when high-speed mechanical blending was substituted for manual homogenization, there was a diminution of observed antigenic activities. The precipitate obtained by addition of acetic acid to the supernates decanted from the test sediments was inactive in our test system.

The test sediments retained activity after suspension in 2 *M* sodium chloride. Appreciable activity remained after rapid freezing to 'dry ice'/acetone temperatures, followed by rapid thawing in a 37° C. water bath. Activity was greatly reduced by suspension in acetate buffered saline, *p*H 5, for about 10 min. The test sediments became inactive after storage overnight at 3° C. in either distilled water or in cold balanced salt solution.

The test sediments were not appreciably soluble in acid solution (up to 18 *N* sulphuric acid), in buffered saline, in 2 *M* sodium chloride, or in distilled water but were dissolved by 0·01 *N* sodium hydroxide and by 6 *M* urea.

The test sediments gave a strong biuret reaction for protein and contained 5–10 per cent of nitrogen by micro-Kjeldahl (dry-weight basis). Alcohol/ether extracts of the sediments contained approximately 1–2 mgm. of chromate-oxidizable material (lipid) per 200–400 μgm. of nitrogen[8] and the residue after extraction contained up to 100 μgm. deoxyribonucleic acid per 200–400 μgm. nitrogen. Hexosamine, N-acetyl-hexosamine, reducing sugars and ribonucleic acid were detectable in small amounts.

The Plasma Proteins in Normal Urine

THE first electrophoretic study of the proteins in concentrated normal urine was published in 1951 by Rigas and Heller[1]. With the aid of the moving-boundary technique, they demonstrated components with mobilities corresponding to those of the main protein fractions in serum. The albumin/globulin ratio was, however, reversed, and there was a poor separation in the globulin range. Other investigators, using moving-boundary or paper electrophoresis, have reported similar results. I have recently subjected the high molecular substances of normal urine to preparative zone electrophoresis[2]. It was found that all urine protein fractions, including the albumin, contained large amounts of carbohydrate, thus differing in composition from the corresponding plasma fractions. Electrophoretic fractionation, therefore, does not give satisfactory information as to the types and amounts of plasma proteins present in normal urine. Immunochemical methods offer better possibilities for identifying individual plasma proteins in urine. Work on the excretion of plasma proteins in normal human urine by immuno-electrophoresis has been published by Grant[3], Patte *et al.*[4], and others. The excretion of about eight different plasma proteins has been demonstrated.

The present work was undertaken in order to identify as many as possible of the plasma proteins excreted in the urines from healthy individuals, and to find out whether immunochemical differences occurred between the urine proteins and the corresponding plasma proteins.

Specimens of filtered 24-hr. urine from 6 male and 6 female healthy students and laboratory workers were concentrated 1,000–1,500 times, using low-pressure ultrafiltration. In some experiments, pooled male urine was also used. The ultrafiltration technique was tested with diluted sera. It was found to give good recoveries of total protein and recoveries of individual proteins without other signs of denaturation apart from some alterations of the lipoproteins. The methods used were immuno-electrophoresis, applying the microtechnique of Scheidegger[5], and the double diffusion-in-gel technique of Ouchterlony[6]. Highly purified plasma proteins (obtained as a gift from Prof. H. E. Schultze, Behringwerke A.G., Marburg/L.) were used as reference substances. A sample of the β_{1A}-globulin, recently isolated by Muller-Eberhard *et al.*[7], was kindly supplied by these workers. Most of the experiments were performed with rabbit antisera (Behringwerke A.G., Marburg/L.) against total human serum and against purified plasma proteins. In some experiments an anti-total-human-serum mule serum (a gift from Prof. P. Grabar, Institut Pasteur, Paris) was also used.

In most instances, eleven to thirteen different plasma proteins were found in the pooled urines as well as in the individual urines. Fig. 1 shows the result of an immuno-electrophoretic experiment with concentrated pooled normal urine and anti-total-human-serum rabbit serum. The electrophoresis was performed at pH 8·2. Twelve or thirteen precipitation lines can be distinguished, probably representing the same number of plasma proteins. This urine also contained the pre-albumin of Schultze[8] and fibrinogen, as shown by specific antisera against these proteins, and thus in total about fourteen or fifteen plasma proteins.

Individual plasma proteins were identified by immuno-electrophoresis, using specific antisera against purified plasma proteins and anti-total-human-serum sera adsorbed with purified proteins, and by the Ouchterlony technique, using specific antisera against purified plasma proteins. By these methods it was possible to demonstrate with certainty the presence of the following plasma proteins in the urines of most of the 12 individuals; the pre-albumin of Schultze, albumin, α_1-seromucoid, haptoglobin, ceruloplasmin, transferrin, the β_{1A}-globulin and γ-globulin. The following plasma proteins were further indicated immuno-electrophoretically: two or three α_1-globulins, in some cases one additional α_2-globulin, regularly one more β_1-globulin and a precipitation line with the same shape and electrophoretic mobility as the β_{2A}-globulin in plasma. Fibrinogen was found in pooled urine and in ten of the individual urines, as revealed by an anti-fibrinogen serum. Ceruloplasmin, the β_{1A}-globulin and fibrinogen do not seem to have been identified earlier in normal urine. Patte *et al.*[4] state that transferrin is the only β_1-globulin present in normal urine. With the present technique, it was possible to demonstrate three β_1-globulins in most of the normal urines. Two of them were identified as transferrin and β_{1A}-globulin. The urine albumin usually showed a somewhat higher electrophoretic mobility than serum albumin in the immuno-electrophoretic experiments, which were carried out at pH 8·2. The same observation was made by Patte *et al.*[4] in pathological proteinurias, but not with normal urine. The reason for this phenomenon is

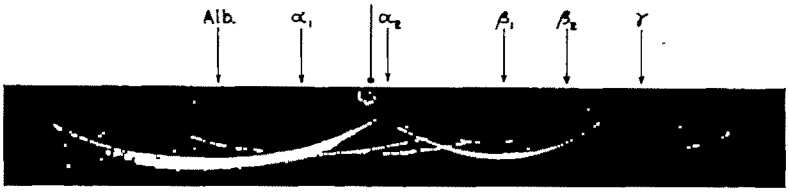

Fig 1

not clear. Experiments with specific antisera against α_2- and β-lipoproteins seem to indicate that these proteins are absent in normal urine. This is in accord with results of earlier investigators. Ouchterlony tests with a specific antiserum against α_2-macroglobulin indicated the presence of traces of this protein in the urines of some of the individuals.

By the use of the Ouchterlony technique and specific antisera against purified proteins, urine was found to contain proteins giving reactions of identity with the plasma proteins pre-albumin, albumin, ceruloplasmin, transferrin, and γ-globulin. Proteins giving reactions of partial identity with plasma globulin seemed also to be present in urine.

A detailed report of this investigation will be published elsewhere.

Steroid 11β-ol Dehydrogenase in Human Placenta

In the course of work on steroid metabolism in pregnancy, we have observed that adrenal steroids with 11β-ol structure are transformed into 11-keto compounds in homogenates of the human placenta at term. The action and properties of the corresponding enzyme have been investigated.

The homogenates were prepared as follows: 5 gm. of wet placenta were ground in an all-glass Potter mill and suspended in 25 ml. of 0·13 *M* sodium chloride buffered to *p*H 7·4 with 0·02 *N* phosphate.

The activity of the enzyme was measured by estimating the percentage of 11-keto compound formed under standard conditions: 1 μgm. of steroid per 1 gm. of placenta (5 ml. of the homogenate), incubated for 30 min. at 37° C., while shaking in a stream of oxygen.

Tritium-labelled steroids were used throughout[1]. The specific activities of cortisol-1,2-^{3}H, of corticosterone-1,2-^{3}H, and of androst-4-ene-11β-ol-3,17-dione, were respectively 835 mc./m.mole, 412 mc./m.mole and 827 mc./m.mole. Dichloromethane extracts of the homogenates were chromatographed on filter paper using the Bush system *C* and/or *B*1 [2]. The radioactivity on the chromatograms was detected and measured in a windowless flow scanner[3].

The membranes (chorion) are a particularly rich source of the enzyme, which appears strongly bound to connective tissue. In homogenates lysed with 0·2 per cent 'Triton', only 30 per cent of the activity remained in the supernatant after centrifuging for 30 min. at 30,000 r.p.m.

The activity in the supernatant could be precipitated in the cold with neutral ammonium sulphate at half saturation. Precipitation at room temperature and precipitation with non-neutral ammonium sulphate both inactivated the enzyme. The activity also disappeared after freezing the tissues.

Table 1

No.	Steroid	Conditions	% conversion
1.	Cortisol	Supernatant with 0·2% 'Triton'	0
2.	,,	,, 0·2 μ*M* DPN added	11
3.	,,	,, 0·2 μ*M* TPN added	33
4.	,,	As No. 3, 10^{-4} *M* mercuric chloride	0
5.	,,	As No. 3, 100 μgm. of cortisone (reaction product) added	38
6.	,,	As No. 3, *p*H 6·01	32
7.	,,	As No. 3, *p*H 7·01	53
8.	,,	As No. 3, *p*H 8·03	66
9.	,,	As No. 3, *p*H 9·1	65
10.	Cortisone	0·2 μ*M* of TPN and 0·1 m*M* of glucose-6-phosphate added. Percentage conversion calculated for inverse reaction.	7
11.	Corticosterone	0·2 μ*M* of DPN added	19
12.	,,	0·2 μ*M* of TPN added	51
13.	Androst-4-ene-11β-ol-3,17-dione	0·2 μ*M* of DPN added	17
14.	,,	0·2 μ*M* of TPN added	36

DPN, diphosphopyridine nucleotide; TPN, triphosphopyridine nucleotide.

The activity of all fractions was suppressed by dialysis for 24 hr. against saline. The activity could be restored by the addition of triphosphopyridine nucleotide. Diphosphopyridine nucleotide also restored the activity, but to a lesser degree.

In the presence of a triphosphopyridine nucleotide-reducing enzyme system (glucose-6-phosphate dehydrogenase) the keto compounds are reduced to the 11β-ol form, indicating the reversibility of action of steroid dehydrogenase.

The enzyme activity shows a broad maximum between *p*H 8 and *p*H 9.

The results are summarized in Table 1. Percentage conversion has been calculated as keto form/(keto form + hydroxy form) × 100.

Finally, it should be pointed out that the 11β-ol dehydrogenase of human placenta has a low substrate specificity since it transforms both C 19 steroids and C 21 steroids with or without a 17-hydroxy group in the side-chain.

The physiological role of the enzyme is uncertain. The conversion of 11-hydroxy group to 11-keto group is a well-known pathway of extra-hepatic steroid metabolism in the animal and in man[4-7].

The placenta enzyme may be part of the regulatory mechanism of the fœtal–maternal endocrine relations. Its presence in the placenta and in the membranes explains the origins of cortisone in normal human amniotic fluid[8].

The technical assistance of Mrs. M. R. Lacroix and Miss Y. Sonnet is gratefully acknowledged. The placenta were kindly supplied by Prof. Schockaert and Prof. Renaer from the Department of Obstetrics and Gynaecology.

Free Amino-Acids of the Tsetse Fly (*Glossina*)

It was discovered some years ago that there is a substantial decrease in the residual (non-fatty) dry weight of the head and thorax of tsetse flies in the course of starvation[1]. Subsequent analysis of flies (*Glossina swynnertoni* Aust.) collected in the field at different stages of the hunger cycle showed that the thoracic residual dry weight decreases by as much as 0·25 mgm. towards the end of the hunger cycle (unpublished work). The findings suggest the existence of a non-fatty food reserve, and since neither glycogen nor reducing sugars could be demonstrated in amounts sufficient to account for these changes in weight, a study of the free amino-acids was undertaken in an attempt to identify the substances responsible.

Amino-acids were extracted in water after precipitation of proteins with ethanol; to avoid contamination with products of digestion in the gut only the head and thorax were used. The extract was evaporated to dryness and taken up in 10 per cent propanol. Amounts corresponding to 1/20 of a tsetse thorax were spotted on Whatman No. 4 filter paper for two-dimensional development with water-saturated phenol and with 77 per cent ethanol at 23° C.

Fig 1*A* shows the free amino-acids of a well-fed *G. morsitans* Westw. captured in the field; those of a similar fly starved to death at high relative humidity are shown in Fig. 1*B*. The chromatogram of the well-fed fly is dominated by an intense alanine spot; glutamic acid also occurs in substantial concentration, with arginine, taurine and serine present in smaller amounts, and glutamine and aspartic acid just detectable. The chromatogram of the starved fly shows a striking decrease in general ninhydrin positivity; a small amount of ornithine has appeared during starvation, the concentration of taurine and serine is about the same, but the alanine, glutamic acid, glutamine and aspartic acid spots have all but disappeared, and the intensity of the arginine spot is reduced.

Preliminary estimates of the amino-acid contents, using Naftalin's colorimetric technique[2], have shown that the disappearance of the alanine spot alone represents a loss of between 0·1 and 0·2 mgm. In other words, the decrease in ninhydrin positivity is quantitatively commensurate with the recorded decrease in residual dry weight, and there can be little doubt that some of the free amino-acids of the thorax of the tsetse do indeed constitute an expendable reserve of food. Viewed in this light it may not be without significance that the de-amination products of the substances concerned (alanine, glutamic acid, glutamine and aspartic acid) are all members of the citric acid cycle.

A comparison has been made between the amino-acid patterns of fed and starved individuals of a few other insects (*Musca* sp., *Lucilia* sp. and *Apis mellifera*). In all of them there is some change in the relative concentration of different amino-acids during starvation, but none shows the striking decrease in ninhydrin positivity which characterizes the tsetse fly. Other blood-sucking insects are at present under investigation, and details of quantitative and comparative results will be published elsewhere.

I am indebted to the Wellcome Trust for a grant towards equipment used in the present investigation.

Sialoadenectomy and the Distribution of Thyrotrophin labelled with Iodium-131

Previous reports from these laboratories[1,2] have indicated the thyroid response to thyrotrophic hormone, as measured by uptake of phosphorus-32 (ref. 3), to be increased in sialoadenectomized animals when compared with intact controls. Hypophysectomy and hypophysectomy plus sialoadenectomy gave identical results as regards iodine trapping by rat thyroid, but the ratio of thyroid organic iodine-131 to inorganic iodine-131 indicated that sialoadenectomy reduced the synthesis of organically bound iodine-131 (ref. 4). To date, our observations have indicated some change in the modus operandi of thyrotrophic hormone in animals whose salivary glands have been removed. To obtain further information regarding the role of thyrotrophic hormone in sialex animals, it was decided to investigate the distribution of labelled hormone therein.

Animal care, feeding, size and preparation were the same as previously described[4]. The thyrotrophic hormone, given by Dr. S. Steelman of the Armour Laboratories, was labelled with iodine-131 by conventional methods[4] with only minor changes. Carrier iodine-127 was kept minimal so that the final iodine to thyrotrophic hormone molecular ratio did not exceed 1 : 100. Under the conditions employed, the radiochemical yield was low (23 per cent) but a high specific activity was obtained. After dialysis, to

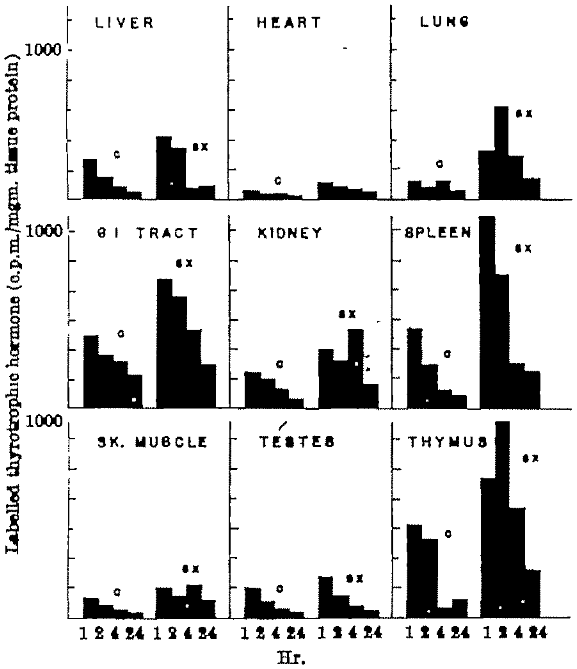

Fig. 1. Distribution of iodine-131 activity following intraperitoneal injection of 5·8 μc./5 μgm. thyrotrophic hormone labelled with iodine-131 to adult male mice. Average results of five animals per group. *C*, intact animals; *SX*, sialoadenectomized animals.

remove free iodide, thyrotrophic hormone content as protein was determined spectrophotometrically by measuring optical density at 280 mμ and comparing with previously calibrated solutions of the original non-labelled thyrotrophic hormone preparation. Radio purity, determined by paper chromatography, was estimated at 98·2 per cent. Bioassay[3] of the labelled thyrotrophic hormone compared most favourably with the original unlabelled hormone, indicating no detectable destruction due to the iodination procedure. The final labelled preparation was diluted with non-radioactive thyrotrophic hormone so that 5·8 μc. of radioactivity corresponded to 5 μgm. of hormone in 0·5 ml. of solution.

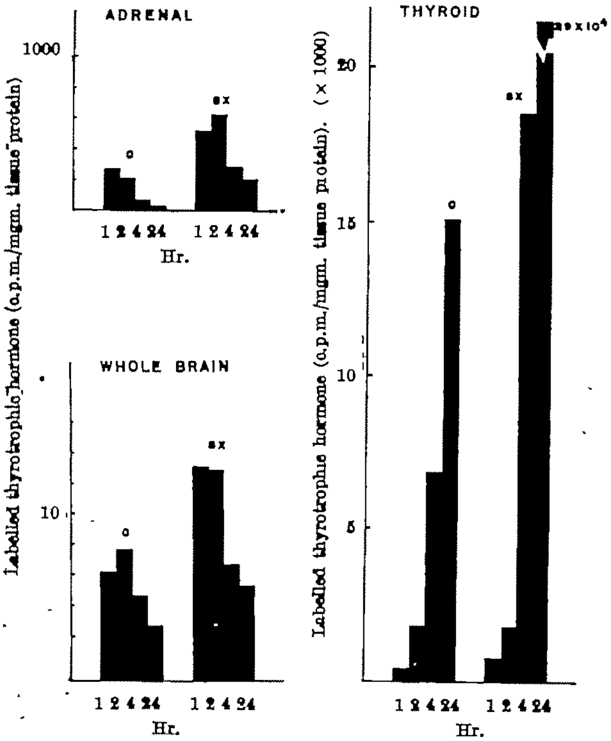

Fig. 2. Distribution of thyrotrophic hormone labelled with iodine-131 in adrenal, brain and thyroid of normal and sialex mice

The thyrotrophic hormone labelled with iodine-131 was administered to adult male mice, intraperitoneally, 5·8 μc. per 5 μgm. per 0·5 ml. Samples of 5 intact animals and 5 sialex animals were taken for analysis at 1, 2, 4 and 24 hr. after injection. Tissue samples, washed free of blood, were homogenized with cold water (1 : 10) and the proteins precipitated with 1 vol. of cold 20 per cent trichloracetic acid. The precipitated proteins were centrifuged, washed with water, alcohol and ether, then resuspended in 3 ml. of saline. The radioactivity of the protein suspensions was measured in a deep-well scintillation counter. The counting was pre-set to give a statistical error no greater than 1 per cent. The protein content of each sample was estimated from the nitrogen content, which was measured by a micro-Kjeldahl procedure. All results are expressed here as counts per minute per mgm. of tissue protein.

The results, indicated in Figs. 1 and 2, show that all the tissues of the sialex mice retained the labelled thyrotrophic hormone (or its degradation products) in higher concentrations than did the intact control animals. After 24 hr., the thyroids of the sialex mice concentrated activity from the thyrotrophic hormone 2·00 times more than did the intact controls, adrenal 5·20, kidney 3·12, heart 3·00, lung 2·73, spleen 2·69, thymus 2·50, liver 2·04, skeletal muscle 1·72, testes 1·69 and brain 1·67. The concentration of activity in the thyroids of both sets of animals exceeded the concentration of all other tissues by factors of at least 9·3 and 7·4 for sialex and intact, respectively. These different tissue concentrations, we feel, can only reflect some profound changes in the metabolism of, and the hormone response by, the sialex host.

The activity appearing in the thyroid is especially interesting, it being the target tissue for thyrotrophic hormone. The very high concentration of labelled thyrotrophic hormone in the sialex animals recalls at once our previous observations[1] regarding the effects of thyrotrophic hormone in these animals. This high uptake in the thyroid is peculiar to labelled hormone since we have not observed any extraordinary uptake when either beef albumin or human albumin labelled with iodine-131 was administered. Decomposition of iodine-131 labelled protein has been shown to be a slow process[6] and should be of little importance in this short-term experiment. We would like to recall the observations of Baker and Abrams[7], which indicated a salivary gland–pituitary relationship to exist. They showed that hypophysectomy resulted in atrophy of the salivary glands and also depressed the enzyme-secreting capacity of zymogenic cells. It is quite probable that sialoadenectomy decreases enzymatic degradation of thyrotrophic hormone, especially in the thyroid as well as in other tissues as the present results seem to indicate. Work by these authors reveals that sialex animals absorb labelled proteins and fats less rapidly than do intact controls, the decreased absorption being related to depressed enzyme activities. On the basis of these observations, our present interpretation is that sialoadenectomy impairs the proteolytic activity of all tissues, especially the thyroid wherein specific proteolytic enzymes exist and which degrade thyrotrophic hormone. The rate of degradation of thyrotrophic hormone would contribute to regulating the rate, and particularly the duration, of action of the hormone. The reduced proteolysis of thyrotrophic hormone in the sialoadenectomized animal results in an extended duration of action. This permits a more pronounced uptake of phosphorus-32, which is due to an increased permeability effect and other phenomena associated with the mechanism of action of the thyrotrophic hormone. Direct measurements of proteolysis in the thyroid of control and sialex animals are needed to confirm this hypothesis.

We wish to acknowledge the technical assistance of Mrs. Nancy Fogel and Robert Sherman.

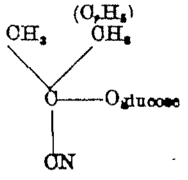
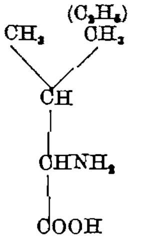
Biosynthesis of Linamarin and Lotaustralin in White Clover

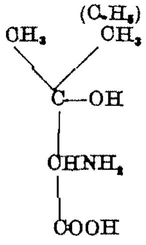
THE strains of white clover (*Trifolium repens* L.) most widely used in New Zealand contain the cyanogenetic glucosides lotaustralin and linamarin (1), which are the glucosides of methylethylketone cyanhydrin and acetone cyanhydrin respectively[1]. Melville and Doak[2] isolated a mixture of the two glucosides from white clover in quantities as high as 1·5 gm. per kgm. fresh material. The pharmacology of these compounds for ruminants grazing on white clover has been studied from the points of view of potential cyanide toxicity[3] and goitrogenic action[4-6].



(1)
linamarin
(lotaustralin)



(2)
valine
(*iso*leucine)



(3)

From structural considerations, and by analogy with the findings of Gander[7,8] on the biosynthesis of *p*-hydroxymandelo-β-glucoside in *Sorghum vulgare*, it was thought likely that the biosynthesis of lotaustralin and linamarin might be related to the metabolism of *iso*leucine and valine (2) respectively. Some preliminary experiments on the biosynthesis of these compounds are reported here.

Four groups of seeds of New Zealand certified white clover were germinated in the dark on moistened filter-papers, to which 10 μc. of one of the following carbon-14 labelled compounds had been added: 1·6 μmole L-*iso*leucine (generally labelled), 2·7 μmole DL-valine-1-^{14}C, 6·5 μmole DL-valine-4-^{14}C and 0·6 μmole glycine-2-^{14}C (obtained from the Radiochemical Centre, Amersham). On the fourth day, the seedlings were transferred to a glasshouse for a further 2 days, after which they were extracted with boiling 80 per cent (v/v) aqueous ethanol for 15 min. The extracts were taken to dryness, shaken with 3 ml. water and clarified by centrifugation. Aliquots of 50 μl. and 150 μl. of each extract were applied in duplicate to Whatman No. 1 filter-papers as adjacent bands and chromatographed in methylethylketone–acetone–water (3 : 1 : 0·6) at 20° C.[9].

Linamarin and lotaustralin in the 50-μl. chromatograms were detected by the following unpublished method, developed by P. Mortimer, Department of Organic Chemistry, University of Adelaide. Each chromatogram was sprayed with linamarase solution (prepared from linseed meal by the method of Coop[10]) and held in a 'Perspex' press adjacent to a similar sheet of paper which had been dipped in picrate reagent[11] and dried in air. A perforated 'Perspex' sheet separated the two papers. The enzyme linamarase hydrolysed both lotaustralin and linamarin with the liberation of hydrogen cyanide and the corresponding ketone. After several hours, orange spots were seen on the picrate papers in areas corresponding to the glucosides. A mean R_F value of 0·59 was observed for linamarin and 0·72 for lotaustralin: glycine, valine and *iso*leucine were found at R_F values of 0·02, 0·10 and 0·18 respectively.

The corresponding areas containing lotaustralin and linamarin on the chromatograms of 150-μl. aliquots were then cut out and eluted with water. The eluates were dried, taken up in 0·5 ml. water and 0·1-ml. aliquots were pipetted on to planchettes. These were dried under an infra-red lamp and counted for radioactivity to 4 per cent error using an end-window Geiger–Muller tube. Aliquots of 0·2 ml. linamarase solution[10] were pipetted on to the planchettes, which were placed in an incubator at 25° for 16 hr. The water and volatile products from linamarase action were evaporated under an infra-red lamp and the planchettes again counted for radioactivity.

The total counts found for the four treatments, expressed in terms of the total plant material, are given in Table 1. Corrections have been made for background counts and for sample geometry; a

Table 1. TOTAL RADIOACTIVITY (COUNTS/MIN. × 10^{-3}, FOR TOTAL PLANT MATERIAL) FOUND IN ELUATES FROM LINAMARIN AND LOTAUSTRALIN REGIONS OF CHROMATOGRAMS BEFORE AND AFTER LINAMARASE ACTION

Amino-acid fed	Before linamarase action		After linamarase action		Radioactivity in aglycone	
	Linamarin	Lotaustralin	Linamarin	Lotaustralin	Linamarin	Lotaustralin
Glycine-2-^{14}C	47	55	41	58	6	−3
L-*iso*Leucine-^{14}C-G	42	270	41	39	1	231
DL-Valine-1-^{14}C	48	20	44	5	4	15
DL-Valine-4-^{14}C	455	61	47	51	408	10

self-absorption correction was not required. The loss in counts after linamarase action corresponded to radioactivity in the aglycone portions of lotaustralin and linamarin respectively; remaining counts could be due to activity in the glucose portions of lotaustralin and linamarin or to activity in other compounds present at these R_F values.

It will be seen that appreciable radioactivity was found in the aglycone portion of lotaustralin when generally labelled *iso*leucine-^{14}C was fed and in the aglycone portion of linamarin when DL-valine-4-^{14}C was fed. Feeding with glycine-2-^{14}C and DL-valine-1-^{14}C resulted in negligible radioactivity in the aglycone portions of both linamarin and lotaustralin.

These findings support the hypothesis that the biosynthesis of lotaustralin and linamarin is related to the metabolism of *iso*leucine and valine, respectively, and that decarboxylation occurs in the process of formation of the cyanide grouping. By analogy with the findings of Gander[7,8], it would appear likely that the corresponding β-OH-amino-acids (3) would be intermediates, but no evidence has so far been obtained for their presence.

This work is continuing and will be reported in detail elsewhere.

BIOPHYSICS

Evidence for Internal Organization of Nucleic Acid in T_2 Bacteriophage

Pellets of T_2 bacteriophage have been found to be liquid crystalline and to be negatively birefringent when subjected to stresses which cause alignment.

A drop of T_2 bacteriophage suspension placed on a microscope slide and covered with a coverslip, when allowed to dry, reveals birefringence at the edge of the coverslip. When the slow direction of the compensator (Red I plate) is aligned parallel to the edge of the coverslip, and both are placed at 45° to the crossed Nicol prisms of a polarization microscope, the birefringent areas appear orange-red, indicative of negative birefringence. Control experiments with drops of tobacco mosaic virus solution, however, produce positive birefringence, in accordance with studies of a similar nature made by Bernal and Fankuchen[1].

The periphery of pellets of these two viruses also exhibits birefringence. Again, when aligned parallel to the slow axis of the compensator, the T_2 bacteriophage indicates negative birefringence while the tobacco mosaic virus demonstrates positive birefringence.

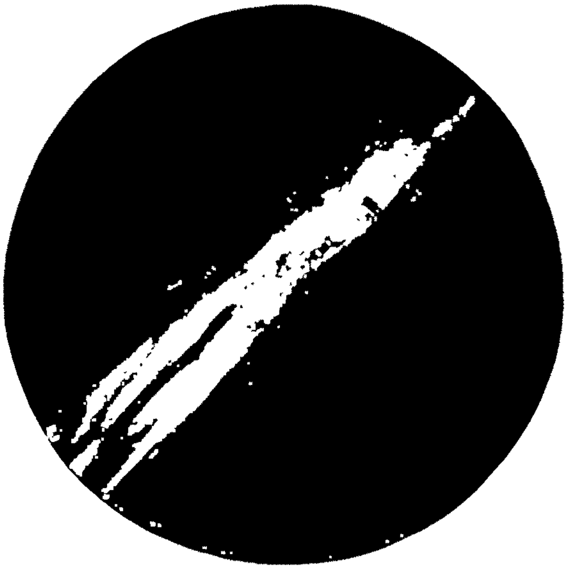

Fig. 1. Photomicrograph of a streak from a T_2 bacteriophage pellet exhibiting birefringence when oriented at 45° to the crossed nicols of a polarization microscope. (× c. 10)

Finally, when material taken from a T_2 bacteriophage pellet is streaked on a microscope slide at 45° to the crossed nicols, it appears orange-red when the slow direction of the compensator is aligned parallel to the streak (Fig. 1). A similarly oriented streak from a pellet of tobacco mosaic virus demonstrates positive birefringence, however, as revealed by a blue colour.

That the birefringence might be the result of extra-particulate deoxyribonucleic acid extruded from the bacteriophage during the manipulative procedures employed prior to the polarization microscopy would appear to be precluded by the following observations. Streaks drawn from pellets of aliquots of a T_2 bacteriophage preparation, one treated and the other untreated with deoxyribonuclease prior to sedimentation in the ultracentrifuge, revealed equally strong negative birefringence. In contrast, streaks from a pellet of an osmotically shocked[2] T_2 bacteriophage preparation, centrifuged sufficiently long to sediment the ghosts but not the nucleic acid, were non-birefringent. When the supernatant fluid from this shocked material was afterwards centrifuged at a force calculated to sediment the nucleic acid, streaks drawn from the resulting pellet were negatively birefringent. An aliquot of this same supernatant fluid treated with deoxyribonuclease yielded a pellet approximately one-fiftieth the size of the undigested material, and streaks of it were non-birefringent. The results of these experiments, therefore, are consistent with the idea that the birefringence is caused by the nucleic acid contained within the bacteriophage particle.

Attempts have been made to demonstrate alignment of the bacteriophage particles within the streak using the electron microscope. Since areas of the streak sufficiently thick to exhibit birefringence with polarization optics were too thick for electron microscopy, the surface of the streak was replicated. It was observed that large areas demonstrate close packing of the particles, as in a crystalline array,

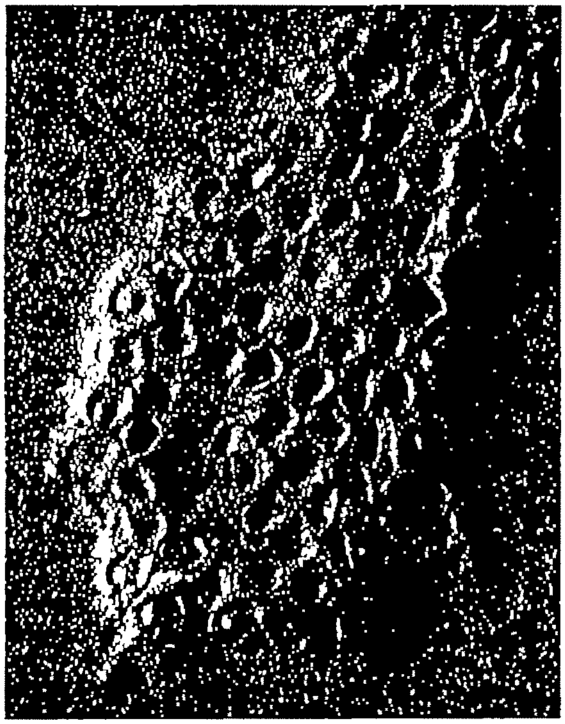

Fig. 2. Platinum preshadowed carbon replica of a streak from a T_2 bacteriophage pellet drawn on freshly cleaved mica (ref. 3) (× c. 75,500)

although the difficulty in visualizing the tails makes it impossible to establish conclusively by electron microscopy that the individual particles are preferentially oriented within the pattern. One such area is shown in Fig. 2. In this picture there is a strong suggestion of orientation with the long axes of the particles lying perpendicular to the shadow direction.

The principal evidence, however, in favour of the orientation of the T_2 bacteriophage particles with their long dimension in the direction of the streak comes from hydrodynamic considerations. As a general experience, when viscous suspensions of anisometric particles are subjected to stretching forces, such as in the streaking experiment described above, the particles are oriented with their long dimension in the direction of the stress. Furthermore, preliminary flow birefringence experiments with T_2 bacteriophage suspensions in pH 5·2 phosphate buffer have indicated negative birefringence, although weak in comparison to the strong positive flow birefringence demonstrated by a tobacco mosaic virus solution subjected to the same velocity gradient. This is, of course, what one might expect in view of the considerably smaller axial ratio of the T_2 virus.

That alignment of rods in a medium of different index of refraction will produce form birefringence independent of whether the particles themselves are intrinsically birefringent was postulated by Wiener in 1912 [4]. Lauffer[5] showed that for tobacco mosaic virus the double refraction of flow decreased in magnitude as the difference in refractive index between that of the virus and the suspending medium decreased. The latter result implies that the flow birefringence produced by tobacco mosaic virus is mostly form and only minimally intrinsic. The fact that T_2 bacteriophage is much less anisometric than tobacco mosaic virus, yet contains considerably more nucleic acid, suggests that its intrinsic birefringence should be of greater significance. The net negative birefringence observed means that the intrinsic birefringence exceeds any positive form birefringence in oriented suspensions of T_2 bacteriophage. Since deoxyribonucleic acid fibres oriented parallel to the optic axis are negatively birefringent, the results thus obtained would indicate that the intrinsically negative birefringent nucleic acid of the bacteriophage is at least partially oriented parallel to the long axis within the virus particle. Preliminary quantitative double refraction measurements indicate that the extent of internal deoxyribonucleic acid orientation is high.

X-ray diffraction patterns of oriented *Sepia* and *Loligo* sperm have led Wilkins and Randall[6] to conclude that the sperm head consists of material possessing a crystalline order. Certain advanced stages in the differentiation of the spermatid of the grasshopper, *Gelastorrhinus bicolor*, have, when sectioned longitudinally for electron microscopy, revealed parallel elements running lengthwise to the long axis of the nucleus[7]. Since the similarity between bacteriophage and sperm has been alluded to by many investigators, one additional similarity may be postulated; namely, alignment of the deoxyribonucleic acid strands within their heads, parallel to their long axes.

We wish to thank Dr. Robert V. Rice, of the Mellon Institute, for making the flow birefringence equipment available.

PHYSIOLOGY

Lipæmic Clearing Action of Artificial Anticoagulants

THE action of heparin in clearing lipæmic plasma is well known[1]. We have investigated the *in vivo* clearing action of several anticoagulants, including heparin, using isotopically labelled fats, and have found that all the anticoagulants tested so far clear lipæmic plasma *in vivo*.

The tests were carried out in man using glyceryl trioleate (triolein) labelled with iodine-131. The fasting subject was given a test meal containing 100 gm. fat which included 50 μc. of the iodine-131 triolein, in the manner described by Ruffin and others[2]. Blood samples were collected over the next 48 hr. Free iodide was removed from the blood samples by exchange resins, and the remaining radioactivity per ml. of blood expressed as percentage of the administered dose. This figure, times the subject's blood volume (70 ml./kgm.), then gave the alimentary

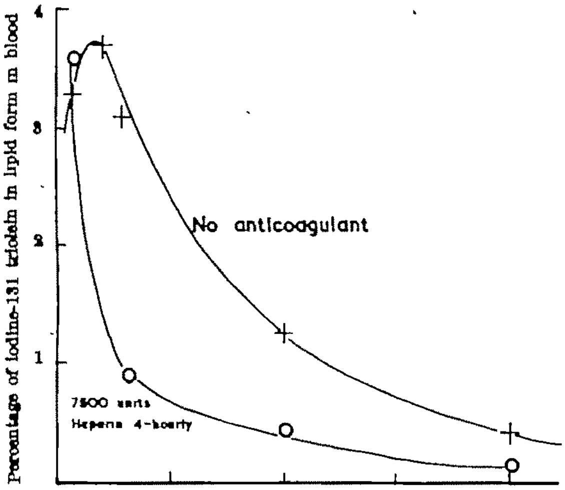

Fig. 1. Effect of heparin on alimentary lipæmia

lipæmia as a percentage of the fat ingested. A typical curve is shown in Fig. 1, upper curve.

The test was then repeated on the same patient while receiving 7,500 units heparin 4-hourly and a typical result is shown in the lower curve of Fig. 1. This response to heparin was found in each of 12 subjects investigated in this way. The curve rises to a maximum in 2–6 hr. The subsequent decline is found to be representable in the form:

$$C = C_0 \exp(-bt) \quad (1)$$

where C is the concentration of tracer fat per ml., t is the time measured from the maximum, C_0 the peak concentration and b, a rate constant.

By plotting the results semi-logarithmically, we extracted the coefficient b and used this as an indication of the rate of lipæmic clearance. In terms of this coefficient, our findings with heparin are summarized in Table 1.

These results are similar to those obtained previously by other methods.

It is generally assumed that the artificial anticoagulants do not clear lipæmic plasma[3]. However, we have found that under the conditions of our experiments the artificial anticoagulants do clear post-alimentary lipæmia *in vivo*. A series of 40 patients has been investigated both on and off anticoagulant therapy using indanedione. In this series phenindione ('Dindevan') and diphenadione ('Oragulant') were used alternatively. The dosage used was adjusted to maintain each patient's prothrombin time within the range 40–60 per cent of his own normal value. The results are summarized in Table 2, and a typical result showing the *in vivo* effect of phenindione is shown in Fig. 2.

This series of 40 subjects comprised patients in hospital following coronary occlusion. The tests were carried out at least 6 weeks after infarction and the order of the consecutive tests (on and off anticoagulant) was randomized. In some cases three tests were carried out on the same subject in the order 'Off', 'On', 'Off' anticoagulant. No change in the lipid tolerance curve was recorded in two cases and a positive effect was recorded in 38 in this series of 40 patients tested while under the influence of indanedione derivatives.

Table 1

	Mean lipæmic clearance constant, b (hr.$^{-1}$)
No heparin	0·09 ± 0·02
Same subjects on heparin	0·24 ± 0·04

Table 2

	Mean lipæmic clearance constant, b (hr.$^{-1}$)
No phenindione or diphenadione	0·09 ± 0·02
Same subjects on either phenindione or diphenadione	0·20 ± 0·04

The importance of determining whether this was a property of the indanedione type of anticoagulant only, or was a property of anticoagulants in general, was suggested to us (Thorp, R. H., private communication).

To this end a further series of six patients was tested while under and while not under treatment with the coumarin derivative 3-(1-phenylpropyl)-4-hydroxy coumarin ('Marcoumar'). The results of this trial are given in Table 3.

Table 3

	Mean lipæmic clearance constant, b (hr.$^{-1}$)
Six patients without anticoagulant	0·07 ± 0·02
Same six patients receiving 3-(1-phenylpropyl)-4-hydroxy coumarin	0·16 ± 0·03

We may therefore conclude that the artificial anticoagulants possess the property of clearing lipæmic plasma *in vivo*. This effect does not appear to depend strongly on the molecular structure of the anticoagulant used. The rate of removal of alimentary lipæmia is approximately trebled by the therapeutic dosage of heparin used, and approximately doubled by the normal therapeutic dosage of artificial anticoagulants.

These results may be related to the efficacy of anticoagulants in the management of post-infarction coronary disease patients[4], in view of the part played by lipids in blood coagulation[5].

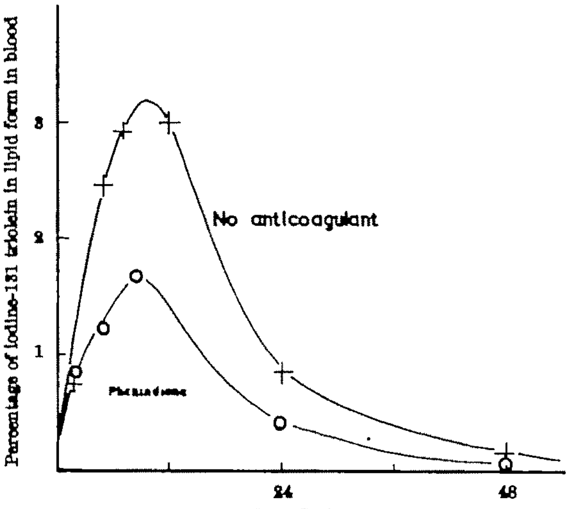

Fig. 2. Effect of synthetic anticoagulant on alimentary lipæmia

Mechanism of the Physiological Action of Rotenone

ROTENONE has been widely used as a poison for the extinction of fish populations. Its action was earlier ascribed to a histolysis of the gills[1] and a blocking of the circulation[2] in the gills. Recently, one of us[3] has demonstrated that these effects are secondary changes due to advanced stages of poisoning.

Excised gill filaments from specimens of *Leuciscus rutilus* L. pretreated with rotenone ($3 \cdot 1 \times 10^{-7}$ *M*) for 8 min. show an inhibition of the respiration of 79 per cent (Warburg experiments, medium Krebs–Ringer solution). Addition of 3×10^{-6} *M* methylene blue to the medium restores respiration up to 83 per cent. Also in mouse liver slices rotenone causes an inhibition of the respiration, a concentration of 160×10^{-7} *M* giving an inhibition of 47 per cent.

In order to gain further information on the point of attack of rotenone, we studied its effect on the respiration of rat liver mitochondria, isolated according to Schneider and Hogeboom[4]. The medium was a sucrose–phosphate buffer *p*H 7·4 (2·0 ml.), containing 50 μmoles phosphate, 10 μmoles magnesium chloride, to which were added 2 μmoles adenosine diphosphate, 80 μmoles glucose, and an excess of hexokinase in order to secure maximum phosphorylation. Each experimental sample contained mitochondria corresponding to 350–400 mgm. wet weight tissue. Rotenone was dissolved in ethanol, the final concentration of which in the experimental samples did not exceed $8 \cdot 4 \times 10^{-3}$ *M*. Succinate or pyruvate was used as substrate, and added in amounts of 60 μmoles per sample. It appears from Table 1 that the respiration of mitochondria is inhibited by rotenone only when pyruvate is the substrate. This inhibition is reversed by methylene blue. In order to find out if the inhibition is caused by a block in electron transport or in oxidative phosphorylation we studied the effect of 10^{-4} *M* dinitrophenol on the inhibition caused by rotenone in the same mitochondrial system as above. This substance did not cause any change in the effect of rotenone upon respiration. Obviously rotenone inhibits electron transport, the block being situated on the substrate side of cytochrome *b*. Viewed against the generally accepted opinion that methylene blue acts as an acceptor of electrons from diaphorase, our results suggest that the block caused by rotenone is located between diaphorase and cytochrome *b*. Difference spectra (Fig. 1) between samples identical with those used in the respiration experiments with pyruvate as substrate, and kept under partial anaerobiosis, show, however, that cytochrome a_3, *a*, *c*, *b* and diaphorase are oxidized in the presence of rotenone. We will not comment at present on these results.

Table 1. RESPIRATION OF RAT LIVER MITOCHONDRIA MEASURED AT 30° C. IN THE WARBURG APPARATUS. GAS PHASE AIR. FOR MEDIUM, SEE TEXT

Substrate	Respiration μl. O_2/30 min.		
	Control	6×10^{-7} *M* rotenone	6×10^{-7} *M* rotenone + 2×10^{-6} *M* methylene blue
Pyruvate (sparker: 3 μmoles glutamate)	112·3	5·5	96·0
Succinate	205·0	217·2	—

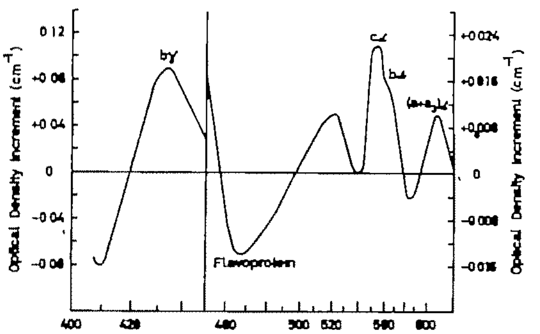

Fig. 1. Spectra representing the differences of absorption between two samples of mitochondria, one of which contained 6×10^{-7} *M* rotenone, registered with the Beckman spectrophotometer *DK*-2. The experimental and control cuvettes contained the reaction media with pyruvate as used in the Warburg experiments. Optical density along the ordinate: to the left for the spectral range 400–450 mμ, to the right 450–625 mμ. Temperature, 22° C. Optical depth of cuvettes, 10 mm.

A detailed report is being published elsewhere.

Financial support from the Fishery Revenue Funds, and a grant from Stiftelsen J. C. Kempes Minne to one of us (K. E. Ö.) are gratefully acknowledged. We are indebted to Dr. Karl-Heinz Kiessling for introducing us to methods for preparing mitochondria and to Prof. Olof Lindberg for valuable discussion.

Influence on the Effect of Vasoconstrictor Amines by Pretreatment with Reserpine

I HAVE examined the influence of reserpine pretreatment (5 mgm./kgm./2 days, intraperitoneal) on the vasoconstrictor action of a series of sympathomimetic amines and of acetylcholine in high concentration, using the hind legs of a rat and Jackson's toad preparation.

The results obtained with norepinephrine, epinephrine, phenylephrine, ephedrine, *d-l*-amphetamine, *d*-amphetamine, and mephentermine confirmed that reserpine potentiates or leaves unchanged the motor effects of catechol or phenolethanolamines, but inhibits those of phenylethanolamines reversibly and those of phenyl or phenolethylamines irreversibly[1].

I found, however, that reserpine in some instances transformed vasoconstrictor effects into vasodilatation. Thus, in animals treated with reserpine, mephentermine produced vasodilatation, instead of vasoconstriction. After similar pretreatment, ephedrine also occasionally produced vasodilatation (3 animals among 20). This effect might be due to an unmasking and/or potentiation of actions on β receptors. In fact, it was found that reserpine not only potentiated the motor effects of norepinephrine but also the inhibitory actions of *iso*proterenol. Pretreatment with reserpine enhanced the vasoconstrictor effect of naphazoline and reduced that of *cyclo*pentamine (without statistical significance). Therefore, these drugs seem to act directly on vasoconstrictor receptors, adrenergic or not.

Acetylcholine in high concentration produces vasoconstriction instead of vasodilatation, by releasing an epinephrine-like substance[2]. I have confirmed this effect and found that it disappeared in animals treated with reserpine.

For comparison I also studied the influence of pretreatment with cocaine on the vascular action of some sympathomimetic amines. In Jackson's toad preparation, the effects of phenylephrine, *iso*proterenol, ephedrine, *cyclo*pentamine and naphazoline, are influenced by cocaine in the same way as by reserpine.

This work was carried out with the aid of a scholarship from the Asociación Argentina para el Progreso de las Ciencias.

Proportion of Noradrenaline to Adrenaline in the Adrenal Glands of Litter-mate Cats

It is well known that the proportion of noradrenaline to adrenaline in the adrenal glands of cats varies considerably from cat to cat. Butterworth and Mann[1] have obtained a range of 13–91 per cent of noradrenaline in the adrenal glands of a group of 38 cats of both sexes. This animal-to-animal variation is in marked contrast to most other laboratory animals, where the proportion of noradrenaline to adrenaline is constant for a given species.

To investigate this variability, litters of healthy, young cats were used. All animals were of such an age as to obviate any factor concerned with an increased noradrenaline content in early life[2]. Each cat was given 120 mgm./kgm. of pentobarbitone sodium, intraperitoneally. Two minutes later both adrenal glands were rapidly removed and an extract prepared in $N/10$ hydrochloric acid. The noradrenaline and adrenaline contents of the extracts were determined by different biological assay techniques, using the cat nictitating membrane and blood pressure as separate test preparations.

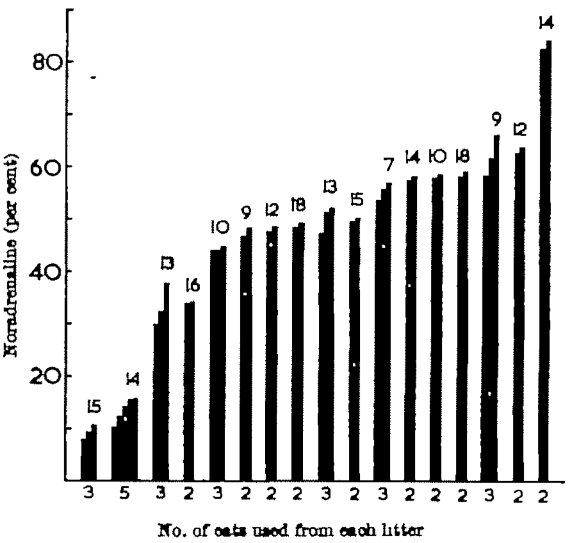

Fig. 1. To show the percentage of noradrenaline in the adrenal glands of litter-mate cats. The numbers at the head of each set of columns indicate the ages in weeks of the cats at the time of removal of the adrenal glands

Fig. 1 shows the percentage of noradrenaline in the adrenal glands of litter-mate cats. 43 animals from 17 litters were used and a range of 8–84 per cent of noradrenaline was found in their glands. This variation was independent of the ages, weights and diets of the animals. However, although there was a wide variation in the percentage of noradrenaline between litters, there was little or no variation within a litter. This is true in every litter studied, and is independent of the size of the litter, the sex and general appearances of the animals.

It appears therefore that, although there is this considerable variability in the percentage of noradrenaline in cat adrenal glands, there is little variation within a litter. Previously it has been necessary to compare the catechol amine content of the adrenal glands of an individual cat, one gland being removed as a control before the experiment is begun. The application of the above observations is that now it is possible to divide litters of cats into test and control groups, in the same way as many other laboratory species are used.

A detailed account of this work, together with information concerning the relationship between the adrenal glands of the parents and their offspring, will be published elsewhere.

Polyenoic Acid in Hypercholesterolæmia induced by Pyridoxine Deficiency in Rats

SINCLAIR[1] first suggested that development of atherosclerosis may be related to the level of polyenoic fatty acids in blood, and, since pyridoxine is known to be a factor for conversion of linolineate to arachidonate[2], atherosclerosis observed in pyridoxine-deficient monkeys[3] may be related to the deficiency of arachidonate. To test the validity of the hypothesis, we decided to make a detailed study of the unsaturated fatty acid content of the blood and of cholesterol and unsaturated fatty acids in the aortæ of pyridoxine-deficient rats and to find whether the hypercholesterolæmia observed had any relationship to cholesterol synthesis in the deficient condition. We have therefore determined simultaneously liver and bile cholesterol, since bile cholesterol is known to reflect faithfully the status of cholesterol synthesis by liver.

Sixty weanling rats were allowed to feed, *ad libitum*, a purified basal diet containing vitamin-free casein 22·0 per cent, sucrose 66·5 per cent, fat (coco-nut oil) 7·0 per cent, salt mixture[4] 2·5 per cent and sulphaguanidine to deplete vitamins. After three weeks, the animals were divided into groups of 20 each. Group I animals received the basal diet supplemented with vitamin mixture; Group II animals received the same diet but the amount of food given was so restricted as to make their growth curves correspond to the Group III animals which also received the same diet with the exception of pyridoxine. After nine weeks the animals were killed. Blood was drawn directly from the heart after opening the thorax, and serum obtained from two such animals were pooled and analysed for polyenoic fatty acids and cholesterol.

For polyenoic fatty acids, serum (2 ml.) was refluxed under nitrogen for 8 hr. with Bloor's mixture, filtered, residue further extracted for an additional 8 hr. under nitrogen, the two extracts mixed, dried over anhydrous sodium sulphate and total lipids re-extracted with 10 ml. petroleum ether. The petroleum ether extract was passed through a silicic acid column[5] (21 × 300 mm.) operating under a slight but constant pressure of nitrogen. The column was then eluted with 350 ml. petroleum ether containing 1 per cent ethyl ether at a rate of about 150 ml. per hr. The solvent was removed from the extract under reduced pressure at 60°, saponified with alcoholic potassium hydroxide, extracted quantitatively with petroleum ether after acidification, made to standard volumes, and 15 ml. were isomerized at 180° with potassium hydroxide–ethylene glycol in reaction tubes[6]. Absorption spectrum was determined in the ultra-violet range of a Unicam *S.P.* 500 spectrophotometer. Concentrations of polyenoic acids were calculated by using the equation of Herb and Riemenschneider[7]. The iodine value was determined in another aliquot. Bile was collected from fistulæ from rats under urethane anæsthesia. For histochemical observations frozen sections of aortæ were used. Unsaturated fatty acids were stained by the bromination method (Sen, P. B., personal communication) and cholesterol was determined by polarization microscopy and by the Schultz techniques.

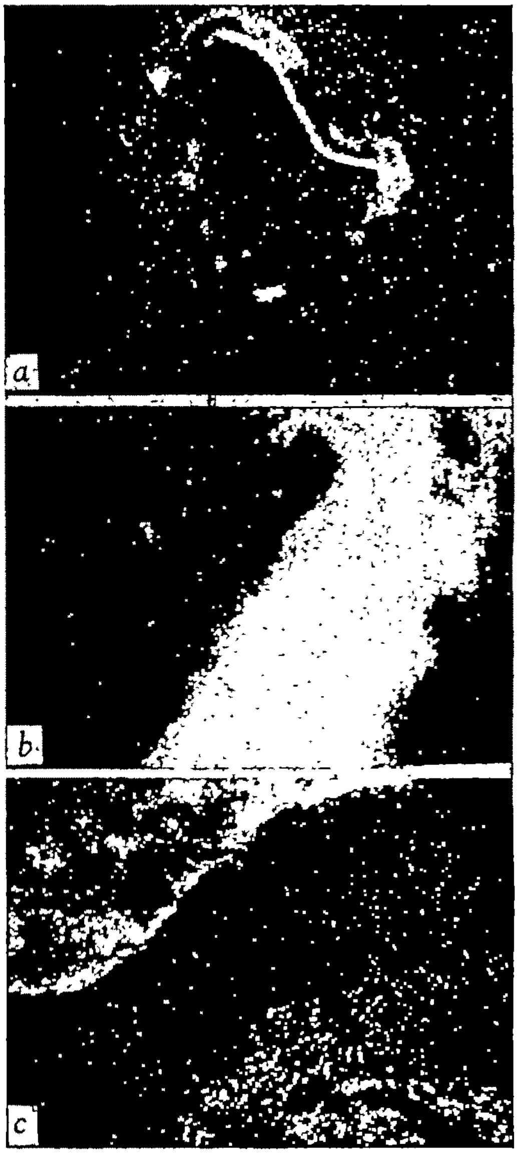

Fig. 1. Sections of aortæ showing *a*, birefringence of intima and media. Note protrusion of intima into the lumen. (× *c.* 100); *b*, intense birefringence of intima around the region of an atheromatous plaque produced in a pyridoxine-deficient rat. (× *c.* 450); *c*, intense Lieberman–Burchard reaction of aortic intima of pyridoxine-deficient rat. (× *c.* 450)

The results are shown in Table 1 and in the photomicrographs (Fig. 1). The Group III animals showed characteristic pyridoxine deficiency morphologically;

Table 1. DISTRIBUTION OF TETRAENOIC ACID IN SERUM, FREE AND ESTER CHOLESTEROL IN SERUM AND LIVER, FREE CHOLESTEROL IN BILE IN MGM. PER CENT AND IODINE VALUE OF SERUM EXTRACT IN THE THREE GROUPS OF RATS

Group	Serum tetraenoic acid	Serum cholesterol		Liver cholesterol		Free cholesterol in bile	Iodine value of serum extract
		Free	Ester	Free	Ester		
I Control	5·7 ± 0·8	43 ± 4·8	60 ± 8	218 ± 15	65 ± 8	12·4 ± 0·2	42·0 ± 1·7
II Inanition	4·4 ± 0·5	40 ± 3·8	55 ± 2	213 ± 11	38 ± 9	9·1 ± 0·3	39·5 ± 2·1
III Experimental	2·3 ± 0·9	62 ± 2·7	112 ± 5	183 ± 17	35 ± 8	10·8 ± 1·4	21·0 ± 6·6

their serum tetraenoic acids were significantly lower and cholesterol deposition in aortæ was also significant. The hypercholesterolæmia appears to be due to increased mobilization from liver, and cholesterol synthesis *in vivo* appears to be unaffected. Staining reactions revealing unsaturated fatty acids did not, however, show significant difference between controls and experimental animals.

We are grateful to the Council of Scientific and Industrial Research for financial assistance and permission to publish, and to Principal K. C. Mukerjee for his interest and advice.

Strain Differences in Acetylcholine Concentration in the Brain of the Rat

WE have recently published results indicating individual and strain differences in cortical and subcortical cholinesterase activity in two strains of rats regularly maintained in the Department of Psychology colony[1]. These strains were developed from a heterogeneous foundation stock by Tryon[2] through selective breeding for maze brightness (the S_1 strain) and for maze dullness (the S_3 strain). The brain cholinesterase activity of the S_1 strain was found to be consistently higher than that of the S_3 strain. More recently, Roderick[3] developed two additional sets of strains of rats differing in cortical and subcortical cholinesterase by a selective breeding programme using the cortical cholinesterase of the sire as the basis of selection. One set was derived from the Dempster and one from the Castle foundation stock of the University of California Genetics Laboratory. Within each set, one strain has a considerably higher brain cholinesterase activity than the other. These four sub-groups are therefore labelled as the *RDH* (Roderick Dempster High cholinesterase) and *RDL*, *RCH*, and *RCL* strains. We thus have three sets of animals, each deriving from a different foundation stock, and each set further subdivided by selective breeding into strains of high and low brain cholinesterase activity.

Our original interest in individual and strain differences in cholinesterase activity stemmed from our observations which indicated a relationship between the adaptive behaviour of the rat and the activity of its brain cholinesterase[4]. We have tended to explain this relationship by reference to the part which the acetylcholine–cholinesterase system plays in transmission at some synapses in the central nervous system, and by assuming that the cholinesterase activity of the brain was highly correlated with its acetylcholine content and would thus give a useful index of the activity of this system. Further work on the relationship between behaviour and cholinesterase indicated that this latter assumption was questionable and led to the hypothesis that the genetic determinants of cholinesterase and acetylcholine were independent (a report of all the relevant behavioural and biochemical data and of the theoretical argument in support of this hypothesis is now in preparation). Fortunately, in the animals already described we had the material at hand to test this hypothesis. If cholinesterase and acetylcholine are genetically linked, then in each set of strain the strain higher in cholinesterase should be higher in acetylcholine.

In this communication we report the preliminary results of a study of the brain acetylcholine content of animals from each of these six strains.

As acetylcholine is a very labile constituent of brain, the technique used for killing the animal and extracting the acetylcholine must eliminate or minimize changes in the 'normal' acetylcholine content. The brain was frozen *in situ* by immersing the rat in a small cage into a large Dewar flask containing liquid oxygen[5]. The brain (excluding cerebellum, medulla, and pons) was removed from the frozen head, weighed rapidly, crushed[6] and then extracted with acidulated alcohol with slight modifications of the technique originally described by Stone[7]. This method of extraction gave a higher yield of acetylcholine than did the use of trichloracetic acid.

The acetylcholine in the extracts was assayed on the rectus abdominis muscle of the frog *R. pipiens*, sensitized with neostigmine bromide[8]. Allowance for the presence of sensitizing substances (which occur in high concentration in brain extracts from animals frozen in liquid oxygen [air][5]) was made by Feldberg's method[9]. Instead of recording contractions of the muscle by a conventional isotonic lever, virtually isometric conditions were imposed by attaching the muscle to a transducer (Statham Instrument Co. model 987-*G7A* ± 0·15 oz.) connected to a Leeds and Northrup 'Speedomax' recorder with a 4-mV. full-scale sensitivity. A 1-gm. increase in tension exerted on the transducer resulted in a full-scale deflexion of the recorder, and this arrangement provided a convenient system which gave reliable and reproducible assays.

All samples were coded and the analysis order was randomized to avoid bias or systematic errors. Duplicate analyses by several different analysts gave similar results.

The results of the acetylcholine determinations are summarized in Table 1. Each high cholinesterase group (the S_1, the *RCH* and the *RDH*) is compared with its corresponding low cholinesterase group (S_3, *RCL*, *RDL*). Table 1 indicates that the acetylcholine concentration ($m\mu M$/gm.) of the S_1 rats is about 14 per cent higher than that of the S_3 strain. This difference is statistically significant at better than the 0·001 level of confidence. Thus, for the Tryon animals, the strain higher in cholinesterase is also found to be higher in acetylcholine. However, the correspondence does not hold for the Roderick animals. For the *RC* rats the high cholinesterase strain (*RCH*) has an acetylcholine concentration which is about 9 per cent higher than the low cholinesterase strain (*RCL*). This difference is significant at the 0·05 level of confidence. The acetylcholine concentration of the *RDH* rats is essentially equal to that of the *RDL* rats. The difference of 0·6 per

P	<0 001		<0·05		n.s.	

cent, which does exist, does not approach statistical significance.

These results seem to support our hypothesis that the genetic mechanisms controlling cholinesterase activity and acetylcholine concentration in rat brain are independent. If this be true, one might expect various ratios of acetylcholine to cholinesterase to occur in Nature. The acetylcholine/cholinesterase ratios cannot be given at present for the six strains, since the tissue samples were not completely comparable for the two types of analyses. For the acetylcholine determination, the brain tissue excluded the cerebellum and the lower brain stem. For the cholinesterase determinations, separate values were obtained for samples of the dorsal cortex and for a subcortical sample which included the cerebellum and lower brain stem. Cholinesterase analyses are now being made on samples comparable to those used in the acetylcholine determinations, and the results will be reported elsewhere. If different ratios occur, this in turn suggests that neither acetylcholine nor cholinesterase alone may be an adequate index of efficiency at cholinergic synapses. Furthermore, another compound intimately involved is choline acetylase. Determination of brain choline acetylase activities in rats of our six strains is planned. This should allow for the testing of our hypothesis that the efficiency of neuronal functioning and adequacy of adaptive behaviour is a function of the balance among choline acetylase, acetylcholine and cholinesterase.

This research was supported in part by a research grant, No. G-2542, from the National Science Foundation, and in part by a research grant, No, M-1292, from the National Institutes of Health, Public Health Services. It also received support from the U.S. Atomic Energy Commission.

Variability in Levels of Blood Uric Acid in Five Species of Birds

OUR preliminary studies on serum uric acid in birds showed the existence of diurnal differences in concentration. Therefore, it seemed appropriate to study the factors associated with these differences. This work is based on 123 birds of four species: *Carpodacus mexicanus*, *Lophortyx californica*, *Passer domesticus* and *Zonotrichia leucophrys*. The birds were housed individually at temperatures ranging from 22 to 26° C. on a daily photoperiod of 5 hr. To test a non-flying bird, week-old chicks kept at 33° C. in a brooder on a 5-hr. photoperiod were used. Water consumption was measured to check the degree of hydration prior to obtaining blood samples. Blood sera were analysed colorimetrically[1]. Activity was induced by (*a*) placing the birds in a cylindrical cage 8 in. in diameter and 24 in. in length and forcing them to hop by slowly rotating the cage at 6 r.p.m. with an electric motor for 2½ hr. or by (*b*) releasing them in mid-air in an empty room illuminated by dim red light. The birds were not attracted by the red light, although we had previously observed them flying towards any stray white light when they were permitted to fly in a darkened room. Because it was impossible to keep the birds flying in the dim red light for more than a few minutes, they were picked up at the end of each flight and re-released a sufficient number of times to give the approximate equivalent of 10 min. continuous flight.

The concentrations of uric acid in the sera of birds of all five species were statistically similar after an 18-hr. period of darkness (Table 1). Levels of uric acid in serum samples removed at the middle of the

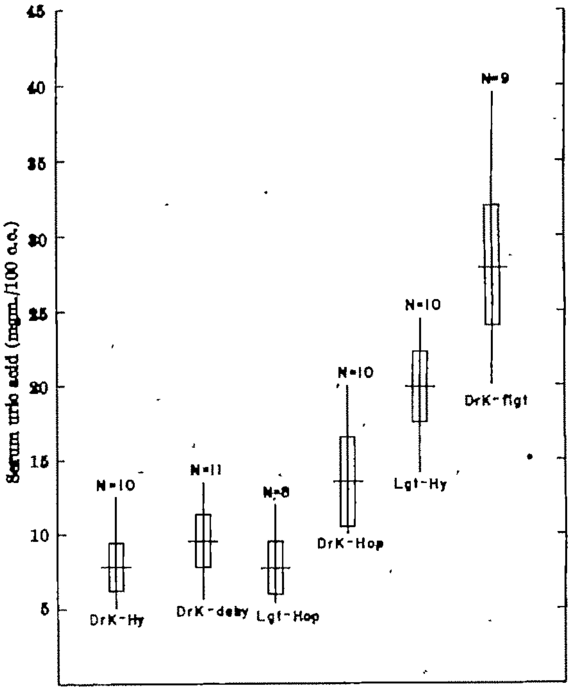

Fig. 1. Serum uric acid levels of *P. domesticus* under different conditions. The vertical lines indicate the range; the horizontal lines indicate the mean ($\bar{x}$); and the rectangles indicate the interval $\bar{x} + 2\sigma_M$ to $\bar{x} - 2\sigma_M$. The number above each line indicates the sample size. *Drk-Hy*, hydrated in the dark; *Drk-dehy*, dehydrated in the dark; *Lgt-Hop*, hopping in the light; *Drk-Hop*, hopping in the dark; *Lgt-Hy*, hydrated in the light; *Drk-flgt*, flight in the dark

photoperiod (after 2¼ hr. of light) were approximately double the value of dark-treated individuals of *C. mexicanus*, *P. domesticus* and *Z. leucophrys* (Table 1), but were unchanged in *G. domesticus*. A high concentration of serum uric acid was found in *L. californica* when forced to fly during the light period. The behaviour of the birds during the light period suggested at least three factors as possible causes of the increase in uric acid: (1) temporary dehydration; (2) light; (3) activity. These factors were tested singly or in combination (Fig. 1) on a single species, *P. domesticus*. Measurements made at the end of the dark period on birds deprived of water for the preceding 24 hr. showed no significant differences from birds which had water available. White light does not appear to be the major cause of elevated uric acid levels during the light period since values from birds forced to hop in the light were among the lowest obtained. We assume that the high values obtained from birds hopping in the dark were caused by their increased activity due to disorientation while being forced to remain active in the dark. The rotation of their cylindrical cage caused some fluttering which was not seen under similar conditions in the light. Birds forced to fly in the dark showed an increase of 3·5 times the mean values of serum uric acid measured at the end of the dark period. The birds frequently flew in their cages during light periods. Thus, it appears that the activity associated with flight is the primary factor in the production of diurnal fluctuations in levels of serum uric acid.

The underlying mechanism for the elevated serum uric acid is unknown. There is the possibility of an increase in protein metabolism during flight[2-5]. Histological evidence for the existence of a renal portal valvular mechanism which could function as a shunt has been found in 24 species of birds including both *Passer domesticus* and *Gallus domesticus*[6]. Thus there is also the possibility that through the action of a renal portal shunt the pattern and volume of blood flow to the kidney are altered during flight and this, together with any increased production of nitrogenous waste, causes the increase in circulating uric acid.

HÆMATOLOGY

Absorption-Elution Grouping of Dried Blood-stains on Fabrics

THE principle of absorption-elution grouping in the ABO system using dried blood smears on microscope slides has already been described[1]. This communication is to show that a similar procedure can be adopted with blood-stains on fabrics. I have used several variations of the method; but that which is most consistently satisfactory is described here.

A fragment of the blood-stained cloth to be examined is cut out with an unstained cloth control, together in one piece of fabric. A convenient size will yield about 10 mm.² of blood-stain and a similar area of unstained cloth. The fabric is plunged into boiling McIlvaine buffer (pH 7·4) for 30 sec. then removed and placed in the antiserum for absorption. Several fragments can be absorbed together in the same antiserum.

Next the cloth is allowed to absorb antibody for 2 hr., then removed and washed three times in saline before being cut into separate stained and unstained fragments. These separate fragments (each about 10 mm.²) are placed separately in the wells of cavity slides (12 mm. diameter wells) and covered by single drops (about 30 µl.) of 2 per cent v/v red cell suspension. The slide is then removed to a moist chamber at 50–55° C. for 5 min. On removal from the moist chamber the slide is rotated vigorously, the fabric pushed to one side of the well and the cells then allowed to stand for 15 min. at room temperature before rotating and reading. Agglutination intensities can be increased by carrying out the final 30 min. of the absorption period at 5° C., and washing in saline at the same temperature.

Results generally parallel those described before[1], but most of my experience in the present work has been with anti-A and anti-B antisera only. My experience of this technique shows that the manipulation involved is only a small fraction of that in using classical absorption-inhibition methods and further that it is a technique which the untrained worker can master very quickly. Points to observe during the use of this technique are:

(1) When fixing, keep the buffer just under boiling point, otherwise with small fragments of fabric the weave is broken up. (2) When fixing and absorbing several stains together either label with water-insoluble ink or rely on the different shapes of the stains used. With very small stains this latter may be the only practical method although different fabric colours often renders labelling unnecessary. (3) Wash well with saline at room temperature. The whole technique depends on efficient removal of uncombined antibody. (4) Efficient elution and agglutination depend on transferring as much antibody from stain to cells as possible. Do not allow the cells to settle before eluting. (5) A convenient warm chamber is made from an inverted Petri dish holding a wet filter paper in the upper part. This is held at 50–55° C. in an incubator. With the small volume of cell suspension used the atmosphere must be saturated with water vapour. (6) The size of blood-stained fragment and cloth control used will vary with many factors, including the amount available, the experience of the operator and the number of antisera employed. As a guide, however, a convenient

size of fabric fragment for each slide well is 5 mm. × 2 mm.

Non-specific Hæmagglutinin from Cellulose and Cellulose Ion Exchanger

IN our work on the fractionation of ether-treated influenza viruses by chromatography on *DEAE*-columns (N,N-diethylaminoethylcellulose)[1] it was found that samples of cellulose exchangers released different amounts of non-specific hæmagglutinin which has to be removed by thorough washing (refs. 1 and 2 and McCrea, J. F., personal communication). We have found similar non-specific hæmagglutinins in batches of normal cellulose, CAM-cellulose and ECTEOLA-cellulose (Schleicher and Schüll, Dassel, Germany; Serva-Entwicklungslabor, Heidelberg, Germany).

With reference to the increasing importance of the cellulose ion exchangers, for example, for fractionation of hæmagglutinating agents[1-3], it seems to be useful to know, and to exclude, this hæmagglutinin.

The dialytic behaviour of the non-specific hæmagglutinin from *DEAE*-cellulose indicates a high molecular weight. The agglutinin was shown to be heat-resistant (½ hr., 100° C.), not susceptible to the receptor-destroying-enzyme, lysozyme, and trypsin, susceptible to sodium periodate, acid and alkali hydrolyses.

Furthermore it is able to agglutinate red cells of different species, for example, rabbit, mouse, chicken, and guinea pig; also human red cells without respect to the blood-group antigens A_1, A_2, AB and O.

The highest agglutinin titre proved to be at *p*H 7·2–7·8. The fixation of the hæmagglutinin to the red cell surface appears to be firm, as proved by hæmolysis on elution. It may be assumed that the agglutinin is a pan-agglutinin and that it belongs to the group of polysaccharides, which is further indicated by its susceptibility to sodium periodate and by a positive Molisch reaction.

The Rh Factor C in South African Bantu

FOLLOWING the recent work of Sturgeon *et al.*[1] on a variant of Rh antigen C common in Negroes, Allen and Tippett[2] on factor G, Wiener and Unger[3] on the complexities of D and Rosenfield and Haber[4] on Rh factor Ce, we considered it timely to undertake a re-appraisal of the Rh factor C in South African Bantu. It was planned to test a series of type Cde Bantu blood donors with a variety of anti-C and anti-CD sera in order to investigate the nature of C and the possible incidence of Allen's G factor. The material consisted of Bantu donors bled during 1959, and, in order to study antibody formation, a series of D-negative Bantu ante-natal patients was also included. In the preliminary stages we referred a number of specimens to Dr. A. E. Mourant for his opinion and we are grateful to him not only for investigating these specimens but also for putting us in touch with Dr. Philip Sturgeon of Los Angeles, who sent us a copy of his paper on the C variant in Negroes and a hitherto unpublished paper extending his original studies; he also gave us a supply of his key serum anti-C^N, which we were able to use for the last five months of the investigation.

The specimens were obtained from healthy male and female Bantu donors and ante-natal cases. We screen all specimens in tubes with two anti-D sera, one complete and one incomplete. Negatively reacting specimens are tested further with from two to four additional anti-D sera, after which a check for D^u variants is carried out by the use of two or three incomplete sera and the indirect antiglobulin technique. The D negatives are screened with saline anti-CD and anti-E sera. Those reacting with anti-CD were tested with a panel of anti-C and anti-CD sera and a small series with anti-C^w. The last 64 Cde donors were also tested with Sturgeon's anti-C^N.

A total of 10,173 Bantu blood donors was investigated of whom 488 proved to be D-negative, and of these 98 gave strongly positive reactions with saline anti-CD sera. On further testing all 98 specimens gave strongly positive reactions with panels of saline anti-C + D sera and sera which contained saline anti-C + albumin anti-D; variable results were obtained with saline anti-C, two giving negative results while three others gave a proportion of positives. No positive results were obtained with anti-C^w. The really significant finding was that not one of the 64 Cde donors reacted with anti-C^N serum although controls on Europeans gave positive results This is in agreement with Sturgeon's findings on Negroes. In order to find out whether there was an antigenic difference between the C of Cde persons and the C of CDe persons, 100 consecutive Rh D-positive Bantu donors were tested for the C antigen; 16 type CDe were found and of these 1 gave a positive reaction with anti-C^N and also strongly positive reactions with the panel of test sera as in the case of European controls, but those negative with anti-C^N behaved as the Bantu Cde type, and it would seem that the Bantu CDe group consists of two types of C, a very small minority conforming to the Caucasian type and the great majority belonging to Sturgeon's Negro variant. One is tempted to speculate that the fifteen anti-C^N negatives belonged to the genotype C^nde/cDe, while the one anti-C^N positive was of the type CDe/cde and, furthermore, that C is a characteristic of Caucasians and not of Bantu.

Of the 365 consecutive ante-natal D negative cases, 50 gave strong reactions with anti-CD sera and 30 of those tested with anti-C^N were all negative. Of 21 D-negative sensitized Bantu females with Rh antibodies, 5 belonged to the 'Negro' type Cde; two of these have not yet been delivered, in two cases the babies required exchange transfusion, and the fifth case was a patient in the country whose baby was severely jaundiced.

In summary, our findings show that of 853 consecutive Bantu D-negative persons, 148 belonged to the type Cde and none to type cdE. This is in keeping with the results reported by Zoutendyk[5] on the Rh types of 300 Bantu. In every case the C resembled Sturgeon's Negro variant in their reactions with saline anti-C sera and in the 94 cases tested with anti-C^N. It was also found that of 50 type cDe tested, none reacted with anti-C^N.

The Rh mosaic has become so confused and complex during the past two years that at present the interpretation of our results can only be speculative. They show that the C factor of type Cde Bantu and most type CDe-Bantu is antigenically different from Caucasian C and one may be able to classify type CDe Bantu into genotypes C^nde/cDe and either C^NDe/cDe or C^NDe/cde according to the reactions obtained with anti-C and anti-C^N sera. Sturgeon[6], in a paper read at the eleventh annual meeting of the American Academy of Forensic Sciences, 1959, has presented evidence that his anti-C^N and the anti-Ce of Rosenfield and Haber are essentially identical reagents, and he suggests the possible interpretation that C^N, c^v, C^n and G may be different expressions of type C.

Whatever the ultimate theoretical significance may be, the immediate practical applications of our findings are obviously important. Tests on Bantu donors should include the use of saline anti-CD sera, and in medico-legal work, for example in tests for disputed paternity, a selected panel of C and CD sera is essential, as not infrequently these cases involve both Europeans and Bantu with a correspondingly complex Rh set-up.

Effect of Heat on the Serum Factors Gm^a, Gm^b, Gm^x and Gm-like

GRUBB[1] reported that Rh-positive red blood cells coated with an incomplete anti-D serum could be caused to agglutinate by serum from some patients with rheumatoid arthritis. He showed also that serum from some healthy patients could inactivate the rheumatoid arthritis serum when mixed with it, so that sensitized red blood cells would not be caused to agglutinate.

Grubb and Laurell[2] showed that the presence of the inhibitor in normal serum is due to a dominant gene (*Gm^a*). Those with the factor are called Gm (a+) and those without it are called Gm (a −). Grubb and Laurell reported also that Gm (a +) sera did not lose their ability to inhibit after exposure to 63° C. for 25 min. but that the rheumatoid arthritis sera were inactivated by such treatment.

We have attempted to repeat Grubb and Laurell's experiments on Gm and to extend them to the other known Gm factors, Gm^b (Harboe[3]), Gm^x (Harboe and Lundevall[4]), and Gm-like (Steinberg, Giles and Stauffer[5]).

		B. Gm (−) sera	
Gm^a	12	12 Gm (a+)	12 Gm (a−)
Gm^b	10	10 Gm (b−)	10 Gm (b−)
Gm^x	16	16 Gm (x+)	16 Gm (x−)
Gm-like	12	12 Gm-like (−)	12 Gm-like (−)

* Heated for 30 min.

All Gm tests were made by the slide technique, described by Harboe and Lundevall[4], using rheumatoid arthritis serum (Bomb.) with anti-D (Ham.) to test for Gm^b, and with anti-D (Warren) to test for Gm-like; and rheumatoid arthritis serum (Bowers) with anti-D (Kimb.) to test for Gm^a, and with anti-D (Ham.) to test for Gm^x (Steinberg, Giles and Stauffer[5]).

We found that undiluted rheumatoid arthritis sera were inactivated and that undiluted Gm (a +) sera were unaffected by heating to 63° C. for 30 min., as Grubb and Laurell had reported. We found, too, that diluting these sera 1/2 or 1/8 with saline did not affect their response to treatment with heat.

Tests with Gm (b +) and Gm (x +) sera indicated that they also remained unchanged when heated neat or diluted in saline. Gm-like (+) sera, on the other hand, became Gm-like (−) and this also was independent of whether the sera were heated neat or diluted in saline. We emphasize, in the light of results to be reported below, that dilution with saline does not affect the above reactions.

Gm (*a* −) and Gm (x −) sera become Gm (a +) and Gm (x +), respectively, when heated neat, but remain unchanged when heated diluted in saline. We have heated one such serum diluted 1/2 in saline for 3 hr. at 63° C. without any change in its Gm type. Gm (b −) and Gm-like (−) sera, on the other hand, remain unchanged on heating. The results are presented in Table 1. Table 2 shows an example of the protocols of the titration of two Gm (a+), two Gm (a −) sera, and a heated Gm (a −) serum.

The change from Gm (a −) to Gm (a +) or from Gm (x −) to Gm (x +) has not been observed in sera heated for less than 15 min. Furthermore, we have noted these changes only when visible aggregates have formed during heating, or on dilution in saline after heating. We have noted, also, that there is a slight positive correlation between the length of time required to form these aggregates and the length of time the serum has been stored at − 20° C. Of the two sera which changed from Gm (a −) to Gm (a +) and from Gm (x −) to Gm (x +) only after heating for 60 min. at 63° C., one had been stored for two months and the other for one year. Neither serum developed visible aggregates when heated for 30 min. but each did so when heated for 60 min. Other sera

Table 2. TITRATION OF TWO GM (A+), TWO GM (A−) SERA AND A HEATED GM (A−) SERUM

Serum	Gm^a	Dilution of test serum 1/4	1/8	1/16	1/32	1/64	1/128	Score
43	+	0	0	0	0	0	++	2

S-14	unheated	+	−	−	−
	heated	+	−	+	−

* The only other Gm phenotypes we have observed are Gm (a + b + x + like −) and Gm (a + b − x + like −), but these do not change on heating.

stored equally long, however, did change after ½ hr. of heating. Attempts to make this observation quantitative, and to analyse the nature of the change in the serum with storage, are planned for the future.

The explanation of the changes in Gm^{a}, Gm^{x} and Gm-like reactivity recorded above is not obvious. Grubb[6] reported that the Gm^{a} factor in normal serum is γ-globulin. γ-Globulin has been shown to be composed of at least two major primary components, one with a sedimentation-rate of 7 *S* and a second with a sedimentation-rate of 19 *S* [7]. Dr. Hugh Fudenberg (personal communication) reports that ultracentrifugation tests show that all four Gm factors of normal serum are located in the 7 *S* γ-globulin and that the 19 *S* component is inactive. Heat is known to aggregate γ-globulin[8]. Hence, after heating it would be expected that there would be a reduction of the amount of 7 *S* γ-globulin and probably a comparable reduction in Gm activity. It is surprising, therefore, that only one factor (Gm-like) becomes negative on heating and that Gm (a −) and Gm (x −) become positive on heating. It is unlikely that the latter change is due to a non-specific interaction of the aggregates with the rheumatoid arthritis serum, of the sort reported by Franklin *et al.*[8], because of the failure of Gm^{b} to change and because of the change of Gm-like (+) to Gm-like (−).

The changes cannot be explained on the basis of antigens competing for the surface of a molecule as has been reported, for example, in *Paramecium*[9], because they are not influenced by the other Gm factors present (Table 3). We hope to be able to submit the aggregated protein to analysis in the ultra-centrifuge.

The different responses of the factors to heat indicate that while they may all be associated with the 7 *S* component of γ-globulin, the molecules for the factors are qualitatively different. At least three molecules or active sites must exist, one for Gm^{a} and Gm^{x}, one for Gm^{b}, and one for Gm-like.

Among white individuals three alleles exist at the Gm locus, *Gm^{a}*, *Gm^{ax}* and *Gm^{b}* (Grubb and Laurell[2], Harboe[3] and Harboe and Lundevall[4]). These three alleles seem to determine two qualitatively different molecules as judged by their reactions to temperature, one for Gm^{b}, and one for Gm^{a} and Gm^{x}. Among Negroes there appears to be an allele *Gm^{ab}* (Steinberg, Stauffer and Boyer[10]) and an allele or a separate gene, Gm-like[5]. It is interesting that Gm (b +) in the Negro as determined by the allele *Gm^{ab}* is stable while Gm-like (+) which appears to be 'serologically' related to Gm^{b} (Sylvia Lawler, personal communication, and unpublished results of the authors) is not. The rare Gm (a −) sera from Negroes become Gm (a +) on heating while the similarly rare Gm (b −) sera from Negroes do not change. This is to be expected because these factors are probably determined by genes from white ancestors.

PATHOLOGY

Inhibition of Aerobic Glycolysis in Yoshida Ascites Hepatoma by Tartronic Acid

THE inhibition of lactic dehydrogenase should allow a blocking of aerobic glycolysis of neoplastic cells, thus depriving them of a high percentage of adenosine triphosphate without damaging the normal cells which, in conditions of normal functional activity and sufficient oxygen supply, do not need this enzyme[1]. According to this premise, the action of tartronic acid, which is a lactic dehydrogenase inhibitor[2,3], on the growth of Yoshida's ascites hepatoma and Ehrlich's ascites tumour was studied[1].

The present experiments were carried out to ascertain what are the tartronic acid concentrations needed to attain *in vitro* a significant inhibition of aerobic glycolysis of the intact cells of Yoshida's ascites hepatoma. Experiments were also performed to ascertain whether parabanic acid, which is a strong lactic dehydrogenase inhibitor of *Bacterium coli*[3], also inhibits aerobic glycolysis of the same tumour.

Each experiment was carried out as follows: 3 flasks (I, II, III) were used, each containing 1 ml. of phosphate buffer solution (*p*H 7·4). In flasks I and II 0·5 ml. of saline containing 1·6 per cent glucose was added. In flask III was added 0·5 ml. of the same solution containing also the acid under test, neutralized with sodium hydroxide. The phosphate buffer solution had been obtained by mixing 43 volumes of 0·154 *M* disodium hydrogen phosphate with 10 volumes of 0·154 *M* sodium dihydrogen phosphate. After having brought the contents of the flasks up to 37°, to each one was added 0·5 ml. ascitic fluid which had been withdrawn immediately before from a rat having borne ascites hepatoma for 7–8 days. Lactic acid concentration was measured in the contents of one of the two flasks (I) without the acid under test, immediately after addition of ascitic fluid; the same determination in the contents of the other two flasks (II and III) was made after 1 hr., during which the flasks were uninterruptedly shaken at 37° in air. Thus the amounts of lactic acid formed with and without the substance under test were assessed. At the end of the experiment care was taken to check the *p*H of the contents of the flasks (II and III) to make sure it had not been modified. For the determination of lactic acid, 0·5 ml. of the contents was removed and poured into 8 ml. of 9 per cent trichloracetic acid solution. After centrifugation the lactic acid content of the supernatant 0·5 ml. was determined by the method of Barker and Summerson[4], taking precautions as suggested by Le Page[5].

It had been established in previous experiments that neither tartronic nor parabanic acid, which may be present in the sample tested for lactic acid determination, interferes with Barker and Summerson's method.

Tartronic acid employed for these experiments was synthesized in the Institute of Organic Chemistry, University of Bologna, according to Bak's method[6] (m.p., 154–156°). Parabanic acid was supplied by the Nutritional Biochemicals Corporation, Cleveland (m.p., 207°).

TARTRONIC ACID

	μgm. of lactic acid formed in 1 hr. by 0·5 ml. ascitic fluid		
Concentration of tartronic acid when present	Without tartronic acid	With tartronic acid	Inhibition (per cent)
10^{-3} M	1,856	1,428	23
,,	612	435	29
,,	816	585	28
,,	1,115	816	27
		Mean values	
,,	1,100	816	26
2×10^{-3} M	1,394	972	30
,,	1,244	830	33
,,	1,244	768	38
,,	979	619	37
		Mean values	
,,	1,215	797	34
5×10^{-3} M	1,856	836	55
,,	952	360	62
,,	748	292	61
,,	1,027	435	58
		Mean values	
,,	1,146	481	58

PARABANIC ACID

	μgm. of lactic acid formed in 1 hr. by 0·5 ml. ascitic fluid		
Concentration of parabanic acid when present	Without parabanic acid	With parabanic acid	Inhibition (per cent)
10^{-3} M	1,802	1,802	—
	925	925	—
2×10^{-3} M	1,074	1,156	—
	864	911	—
5×10^{-3} M	1,217	1,312	—
,,	639	714	—
,,	1,020	1,020	—

Results are given in Table 1. It appears that while the amounts of lactic acid produced are subject to considerable variations from one experiment to another, comparison of the lactic acid produced in each single experiment by the same ascitic fluid with and without tartronic acid shows a constant ratio. Variations in the production of lactic acid from one experiment to another are in close relationship, as was seen in previous unpublished experiments, with the amount of neoplastic cells in the ascitic fluid, which is greatly different from animal to animal.

The present experiments show that concentrations of 10^{-3} M, 2×10^{-3} M and 5×10^{-3} M inhibit the aerobic glycolysis of Yoshida's ascites hepatoma at a rate of 26, 34 and 58 per cent, respectively. On the contrary, parabanic acid, even at a concentration of 5×10^{-3} M, has no inhibitory action on the aerobic glycolysis of this tumour.

Further experiments will be carried out to ascertain what concentrations of tartronic acid can be attained *in vivo*. Of interest in this connexion is the observation[7] that tartronic acid is not transformed by animal tissues, and that 15 hr. after intramuscular administration of 40 mgm. tartronic acid in the rat, only 27 per cent is found in the urine.

The Ouchterlony Technique using Antigen or Antiserum labelled with Iodine-131

THE Ouchterlony agar plate technique[1] has been used a great deal for the analysis of antibody–antigen systems, but it was not until recently that it was used quantitatively[2]. An autoradiographic agar plate technique employing radioactive proteins has been described by Perlmann and Hultin[3] for the demonstration of proteins in complex systems, but their method was not in any way quantitative.

A quantitative method employing either antigen or antiserum labelled with iodine-131, cellulose acetate paper, and autoradiography has recently been found useful for certain purposes in our laboratory.

In an earlier series of studies, agar was used as the diffusion medium. 4 ml. of 2 per cent agar was distributed in a thin layer (about 1 mm. thick) on a glass slide. The antigen and antiserum were placed in small holes in the agar opposite each other, and the slide was left to stand in a moist atmosphere for some days. Free antigen and antibody were washed out by immersing the slide in saline containing merthiolate for 1–2 days. It was then dried and placed in contact with an X-ray film for a few days. The distribution of bands of radioactive antibody–antigen precipitate could clearly be seen on the developed film. Afterwards it was found more convenient to use cellulose acetate paper instead of agar as diffusion medium (suggested by Kohn, J., personal communication). The details of the procedure are as follows: Strips or disks of 'Oxoid' cellulose acetate paper ('Oxoid' membrane filter strips and disks obtained from Messrs. Oxo, Ltd. (Med. Dept.), 16 Southwark Bridge Road, London) of the appropriate dimensions are prepared as follows: A ball-point pen is used to mark the spots on each strip where the antigen solution and antiserum are to be placed. For example, in the case illustrated in Fig. 1, a row of 8 dots about 1 cm. apart was made for the antigen and another parallel row, with the same spacing, was made for the antiserum 0·8 cm. from the antigen row. The strip is 'floated' on phosphate buffer pH 7·6 so that the liquid soaks in of its own accord. It is then taken out and 'blotted' on filter paper. The antigen and antiserum solutions are then applied to the appropriate spots in 1-μl. quantities with a micro-constriction pipette. Either the antigen or the antiserum is labelled with iodine-131. As soon as all the solutions have been applied the strip is placed in oil 'Whitemor 120' (kindly supplied by the Manchester Oil Refinery (Sales),

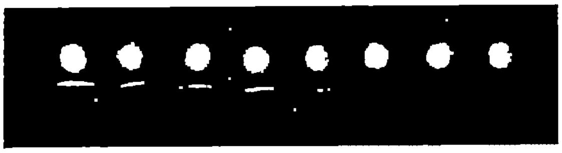

Fig. 1. Autoradiograph of the reaction between human serum albumin (labelled with iodine-131) with rabbit anti-human albumin serum on cellulose acetate strips. Labelled human serum albumin 0·5 µgm./µl. was used as antigen. 1 µl. antigen was applied to the cellulose acetate paper 0·8 cm. from 1 µl. of the serum dilutions. Rabbit anti-human albumin serum diluted as follows: 1/1, 1/4, 1/16, 1/64, 1/128, 1/256, 1/512, and 1/1,024 beginning at the left-hand side

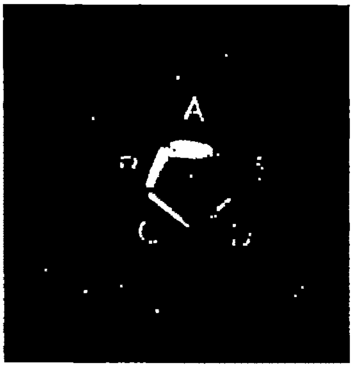

Fig. 2. Autoradiograph of the reaction between human serum albumin labelled with iodine-131 with dilutions of rabbit anti-human albumin serum on cellulose acetate disk. 2 µl. iodine-131 labelled human serum albumin (0·5 µgm./µl.) were placed in the centre. 1 µl. of the serum dilutions was applied 1 cm. from the centre. *A*, 1/1 dilution; *B*, 1/4 dilution; *C*, 1/16 dilution; *D*, 1/64 dilution, and *E*, 1/128 dilution

Ltd., 76 Jermyn Street, London, S.W.1) for 24 hr. (Kohn, J., personal communication), after which it is removed, quickly rinsed in ether, and put into phosphate buffer, *p*H 7·6, for 2–4 hr. After the strip has been allowed to dry completely between two pieces of filter paper it is placed in direct contact with an X-ray film ('Kodirex') in complete darkness for a few hours or a few days depending on the specific activity and quantity of the material labelled with iodine-131. The film is developed by the usual procedure.

Figs. 1 and 2 show typical pictures obtained when a constant amount (0·5 µgm./µl.) of human serum albumin labelled with iodine-131 was applied to strips or disks of cellulose acetate and tested against twofold and fourfold dilutions of rabbit anti-human albumin serum. The last dilution of antiserum to give a detectable precipitate in Fig. 1 contained about 1 µgm. antibody nitrogen/ml.

Similar results were obtained when rabbit γ-globulin against human albumin was labelled with iodine-131 (according to the technique of McFarlane[4]) and tested against unlabelled human serum.

The advantages of this procedure are sensitivity and that it requires only very small amounts of antiserum and antigen.

Pathogenicity of *Metarrhizium anisopliae* (Metch.) Sor. and *Beauveria bassiana* (Bals.) Vuill. to Two Species of Elateridae

DURING 1950–59 numerous elaterid eggs, larvæ, pupæ and adults died and became 'mouldy' in rearing or storage at the Saskatoon Research Station. Seven fungi were isolated from such specimens in 1959. In initial screening trials, only two of these, *Metarrhizium anisopliae* isolated from a larva, and *Beauveria bassiana* from an adult of *Hypolithus bicolor* Esch., increased the rate of mortality of this elaterid and of *Ctenicera aeripennis destructor* (Brown). These fungi have not been recorded previously from *H. bicolor*, and *Beauveria* has not been recorded from *C. a. destructor*. It was of interest, therefore, to determine whether they are primary pathogens of these elaterids.

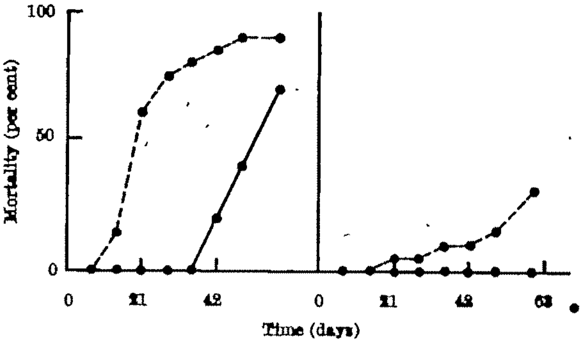

Fig. 1. The mortality of *Hypolithus bicolor* (left) and *Ctenicera aeripennis destructor* larvæ in soil infested with *Metarrhizium anisopliae* (– – – –), and not infested (———)

Larvæ that were in, or near, the last instar and female adults were collected in the field and stored at 5° C. For the tests, the larvæ were placed in soil in individual salve boxes, and the adults on blotting paper in plastic boxes, five of each species per box. They were exposed to the fungi by uniformly infesting the soil in which the larvæ were placed and by spraying

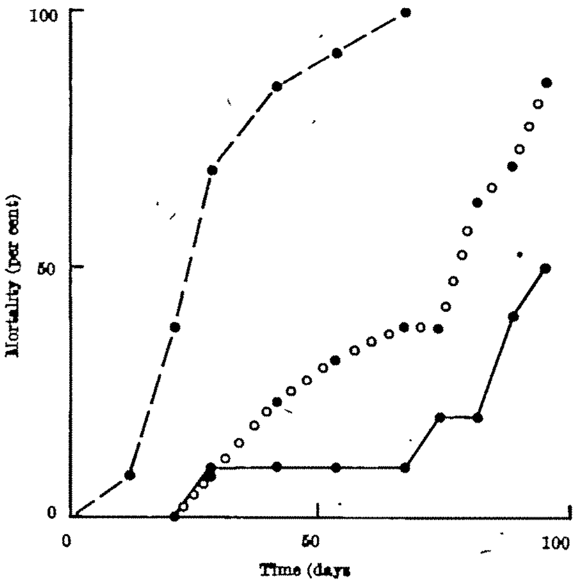

Fig. 2. The mortality of *Hypolithus bicolor* larvæ in soil infested with *Metarrhizium anisopliae* (– – – –), infested with *Beauveria bassiana* (o o o o), and not infested (———)

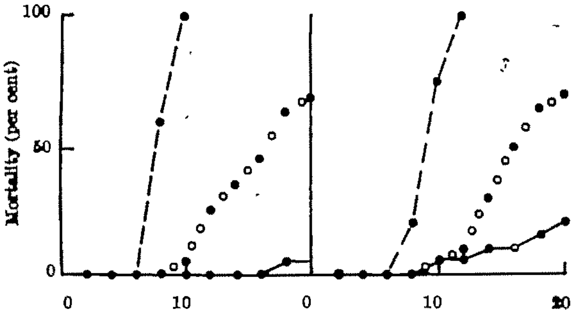

Fig. 3. The mortality of female adults of *Hypolithus bicolor* (left), and *Ctenicera aeripennis destructor*, inoculated with *Metarrhizium anisopliae* (– – – –), *Beauveria bassiana* (o o o o), and uninoculated (———)

the adults directly with aqueous suspensions of spores. The suspensions were prepared from cultures of the fungi on a glucose–nitrate agar medium. Generally in a test the numbers of larvæ or adults of a species were 10 in the control and 20 in the treated series. The insects were kept at 20° C. during the tests.

As shown in Fig. 1, *Metarrhizium* increased the rate of mortality of the larvæ of the two elaterid species, but the larvæ of *C. a. destructor* appeared more resistant to it than were those of *H. bicolor*. *Beauveria* increased the rate of mortality of *H. bicolor* (Fig. 2). In an initial screening test it did not increase the incidence of mortality among larval populations of *C. a. destructor*. Both fungi increased the rate of mortality of the adults of the two elaterid species, which appeared about equally susceptible (Fig. 3). *Beauveria* was less virulent than *Metarrhizium* to the larval (Fig. 2) and adult (Fig. 3) stages of the elaterids. The respective fungi were re-isolated, even after surface disinfection, from the majority of larvæ and adults that died in the treated series. The fungi were not obtained from the dead insects of the control series. The results therefore indicate that the two fungi are primary pathogens of one or more stages of *H. bicolor* and *C. a. destructor*.

Metarrhizium anisopliae and *B. bassiana* have been reported from other elaterid species[1-5], but tests indicated that they were generally only mildly virulent[3,4,5]. It is interesting to note, therefore, that these fungi are highly virulent to some stages of the two most common elaterid species in Saskatchewan, and that they differ in virulence to species and to stages within a species. Further work is in progress to determine the nature and extent of these differences.

We are indebted to Dr. D. M. MacLeod for confirming the species identification of the fungi.

A Rapid Method for studying Tumour Blood Supply using Lissamine Green

Goldacre and Sylvén[1] have described a method for making visible those regions of solid malignant tumours supplied with flowing blood. They used a high blood concentration of the triphenylmethane dye, lissamine green (Gurr), which turned the whole animal green except where there were barriers. Ten to twelve days following the transplantation of sarcoma 37, mammary carcinoma and Erhlich Landschutz tumours in mice and Walker sarcoma in rats it was observed that vascular obstruction occurred, confining the flowing blood to a thin surface layer of the tumour. Tumours measuring 1–3 cm. across had a white centre and a green periphery. The dye does not penetrate the living cell membrane but the surrounding tissues become green due to the green blood in them and the green interstitial fluid derived from the blood. Extensive regions not supplied with flowing blood but with a thin coating layer supplied with blood were also found in various large spontaneous and methylcholanthrene-induced tumours of rodents. Cells dissected out from the non-coloured tumour region were found to be dead except when within about 300μ from the green region, where mixtures of living and dead cells were found.

As an extension of this work, lissamine green 2 per cent solution in Ringer's solution is being used to study the blood supply in spontaneous tumours occurring in the dog and cat. Preliminary experiments with rats and mice, injecting 1 ml. into the tail vein in mice and 8 ml. in rats, confirmed that the whole animal turned green except for the brain and the spinal cord, the interior of the eye, the material on the fœtal side of the placenta, and to a large extent the testis, ovary and mammary gland. Essentially the same picture has been found after intravenous injection of the dye in the guinea pig, cat and dog. Smaller quantities of the dye—2–4 ml. per kgm. body-weight—have been used in dogs and cats. This does not appear to be toxic, as one normal dog showed no ill effects and the green colour had disappeared within 48 hr. Postmortem examination of the injected dogs showed the testicles to be green, though paler than in many other tissues. Using this lower concentration of dye in the blood stream, the liver and lungs retained some of their original colour. The pituitary and meninges were green but no green colour crossed to the brain. An area of hæmorrhage and necrosis in a cerebral hemisphere of one dog remained free from green coloration.

Three cats and five dogs affected with spontaneous tumours were anæsthetized with sodium pentobarbitone and injected intravenously with 2 per cent lissamine green in Ringer's solution. 3–5 min. later a lethal dose of sodium pentobarbitone was given intravenously and postmortem examination carried out. Table 1 shows the tumours studied and the results. There was complete or almost complete distribution of lissamine green throughout the tumour tissue in squamous cell carcinomas in cats. A similar picture occurred in a lipoma in a dog and in all metastases less than 1 cm. across in the lungs and kidney arising from an osteo-sarcoma of the humerus in a dog. The distribution of lissamine green in other cases showed that some vascular obstruction occurred near junctions of viable and necrotic tumour tissue. Thus in the large (14 cm. diameter) osteo-sarcoma of the humerus there was a diffuse green distribution

Table 1

Tumour	Location	Primary	Secondary	Green	Not green	Remarks
Squamous cell carcinoma. Cat	Larynx	*		*		Few scattered small white areas 1 mm. across
	Submaxillary lymph node		*	*		
Squamous cell carcinoma. Cat	Pharynx	*		*		Few scattered small white areas 1 mm. across
Squamous cell carcinoma. Cat	Tonsil, pharynx, tongue	*		*		Few scattered small white areas 1 mm. across
	Retropharingeal lymph node. Lungs		*	*		
Lipoma. Dog	Shoulder	*		*		Tumour size, 10 cm. × 12 cm × 7·5 cm.
Osteosarcoma. Dog	Humerus	*		*		Thin layers surrounding cysts pale green or white
	Lungs		*	*	* One metastasis 3 cm. across	Size, 0·1–1 cm., all green
	Kidney		*	*		
Seminoma. Dog 1	Testicle	*			*	White, with few small areas of pale green
Seminoma. Dog 2	Testicle	*			*	
Spheroidal-celled carcinoma. Dog	Subcutaneous thorax. Ribs 2–6	*			*	7 cm. × 3·5 cm. Dark red. 0·5 cm. at periphery and intersecting connective tissue green
	Lung		*	*		1 cm. across. Some central areas grey-white

throughout the tumour, except for areas of 1–3 mm. thickness surrounding cysts and occurring mainly in the centre of the tumour mass. The large number of lung metastases, 0·1–1 cm. diameter, stood out sharply as round, deep green lesions, in contrast to a background of pink and pale green lung tissue. One larger metastasis about 3 cm. in diameter was full of caseous white material and surrounded by non-green tumour tissue except at the extreme periphery. Seminomas remaining white were found on histological examination to be essentially cellular with little other tissue. Smaller areas appearing green were nearly all connective tissue. A spheroidal celled carcinoma in an old dog showed a striking colour contrast similar to that described by Goldacre and Sylvén[1] in malignant tumours of mice. This large circular tumour with central necrosis and hæmorrhage extended a distance of about 7 cm. in the deep subcutaneous tissues from the second to the sixth ribs. A peripheral layer of about 0·5 cm. and the intersecting connective tissue in the tumour substance were green. The remainder of the tumour was dark red. Secondary deposits in the lungs were green, some showing grey-white areas centrally.

This vascular obstruction or blood tumour barrier is not strictly comparable to the blood brain barrier. Goldacre and Sylvén found that dyes such as neutral red and methylene blue, while having a similar distribution in tumour tissue, were unlike lissamine green in that they entered the brain. Recognition that this blood tumour barrier may occur in some spontaneous tumours of domestic animals but not in others is of fundamental importance in the attempted treatment of neoplasia when surgery is not practicable. In those tumours showing complete green coloration it would be theoretically possible, using systemic chemotherapeutics, to destroy all the malignant cells. In other tumours, viable cells lying between the necrotic centre and the periphery of the tumour would be exposed to a relatively low concentration of drugs administered systemically, thereby seriously interfering with cancer chemotherapy.

I wish to thank Mr. A. R. Jennings for help with the histological examination of these tumours.

IMMUNOLOGY

6-Mercaptopurine in Immunological Responsiveness

Schwartz and Dameshek[1,2] have reported the apparent production of immunological tolerance in rabbits by the administration of a purine analogue, 6-mercaptopurine. Rabbits receiving concomitantly human serum albumin and 6-mercaptopurine failed to develop an immune response to the protein antigen, and weeks later, when antigen alone was administered, the animals remained tolerant. In an effort to confirm this finding and to explore the possible effects of 6-mercaptopurine on homografts in rabbits, two groups of rabbits received injections of ovalbumin in Freund's adjuvant and were grafted with skin from a common donor rabbit. One of these groups received 6-mercaptopurine in the maximum dose employed by Schwartz and Dameshek, the other group serving as controls. The 6-mercaptopurine did not produce immunological tolerance for ovalbumin nor did it result in successful homografts.

Each of seven New Zealand rabbits, weighing approximately 2 kgm., received a small homograft of

Table 1. SUMMARY OF IMMUNOLOGICAL RESPONSES OF CONTROL ANIMALS AND ANIMALS TREATED WITH 6-MERCAPTOPURINE

PCA, Passive cutaneous anaphylaxis.

skin from the back of a common donor rabbit on to a site prepared on the left ear. Similarly, an autograft of skin from the back of each rabbit was sutured into a site prepared on its own right ear. Four of these animals received daily intramuscular injections of 6-mercaptopurine (6 mgm./kgm./day) for 14 days, the first injection being given the day prior to operation. Three rabbits served as controls. On the third and the tenth post-operative days, a mixture of ovalbumin (8·4 mgm. ovalbumin nitrogen) and complete Freund's adjuvant was injected subcutaneously. Those animals surviving for 21 days were bled on the fourteenth and twenty-first days. Two of the rabbits treated with 6-mercaptopurine died within 20 days of operation. One of the rabbits (No. 32) receiving 6-mercaptopurine was re-injected subcutaneously with ovalbumin and Freund's adjuvant on the forty-eighth day and on the fifty-sixth day after operation. On the sixty-first day after operation, this animal was bled again. The skin grafts were observed at intervals throughout the period of the study.

Analyses for anti-ovalbumin antibody included: (1) quantitative precipitin studies[3], and (2) passive cutaneous anaphylaxis[4]. In the latter method, dilutions of sera (1 : 20 to 1 : 640) were injected intradermally (0·1 ml.) into guinea pigs. Two hours later, 5 mgm. of ovalbumin in 1·0 ml. of 1 per cent Evans blue dye were injected intravenously. Thirty minutes after injection of antigen, the animals were killed and the extent of bluing noted. The passive cutaneous anaphylaxis titre was that dilution of serum which gave an area of bluing of 5 mm. or more in diameter.

Results are summarized in Table 1. The sera of control animals contained precipitins against ovalbumin (both 14-day and 21-day bleedings). Precipitating antibodies were not detectable in the 14-day sera of the 6-mercaptopurine-treated animals and the potentially more sensitive passive cutaneous anaphylaxis reactions were negative. One of the two animals treated with 6-mercaptopurine that survived beyond 21 days had precipitins demonstrable in the 21-day serum, and the other rabbit (No. 32), when restimulated with ovalbumin and adjuvant, developed precipitating antibodies. Homografts were rejected in all animals living beyond 21 days. Rabbit No. 32, which had the poorest initial immunological response to ovalbumin, had the longest surviving homograft (35 days). Autografts were successful in all animals.

The number of animals in the present study was small. The two animals treated with 6-mercaptopurine that survived beyond 21 days developed serum precipitins against ovalbumin, although there was unequivocal suppression of immune response during such treatment. The difference between these results and those of Schwartz and Dameshek is probably related to the method of antigenic stimulation. Incorporation of an antigen in complete Freund's adjuvant provides a maximal stimulation, while a single intravenous injection of a soluble protein antigen is a weak stimulus. During treatment with 6-mercaptopurine, animals lost varying amounts of weight (average loss 14 per cent initial weight). (Not included in the table of results were three additional rabbits treated with 6-mercaptopurine that died before completion of their course of the drug.) The lesser immunological response during administration of 6-mercaptopurine may be an expression of general inanition of the animals rather than a specific alteration of nucleic acid metabolism.

This work was supported in part by a grant from the U.S. Public Health Service.

Note added in proof. Delayed rejection of homografts with 6-mercaptopurine treatment and the failure of 6-mercaptopurine completely to suppress antibody formation, when antigen was incorporated in Freund's adjuvant, have been noted in recent reports (Meeker, W., *et al.*, *Proc. Soc. Exp. Biol Med.*, 102, 459 (1959); and Hoyer, L., *et al.*, *Fed. Proc.* 19, 208 (1960).

BIOLOGY

Expanded Ilio-Sacral Joint in the Toad *Xenopus laevis*

THE pelvis of Salientia is characterized by very long ilia which connect with transverse processes of the sacral vertebræ. In some Salientia these processes are greatly expanded laterally. The functional significance of this modification was, however, not clear[1].

The pipid species *Xenopus laevis*, the South African clawed toad, provides an interesting example of this modified condition. The Pipidæ are non-jumping but powerfully swimming forms; the upper (anterior) ends of the two ilia are in contact over a large area with the lateral edges of the expanded wing-like transverse processes of the sacral vertebra (Figs. 1*a* and *b*). Green[2], Gadow[3] and Grobbelaar[4] regarded this contact as a more or less rigid joint; Ridewood[5] and Nauck[6], on the other hand, described the joint as movable though without commenting on its musculature.

Dissection of a freshly killed *Xenopus* shows that the vertebral column slides freely backwards and forwards on the pelvic girdle, in a groove in the medio-dorsal aspect of the ilia. In the living animal a slow-motion cinematograph film revealed a 20 per cent range of extension and contraction of the total body-length as a result of this movement; in one specimen the 'normal' trunk-length of 9·5 cm. could be contracted to 8·5 cm. or, when the hind-feet pushed against a solid surface, expanded to 10·0 cm.

Two pairs of muscles control this movement (Fig. 2). The coccygeo-iliac muscles (*A*) serve to extend the body by projecting the trunk forwards in relation to the anterior surface of the ilia. The ilio-lumbar muscles (*B*) draw the pelvic girdle forwards with respect to the vertebral column. This pair has its insertion on the lateral aspect of the ilia. There are two positions of origin (i) from the latero-ventral side of the 2nd–5th vertebræ, as in *Rana*, and (ii) from backwardly curving processes from the 4th vertebræ. These processes are derived from the ribs of the tadpole and are found also in *Pipa*[1].

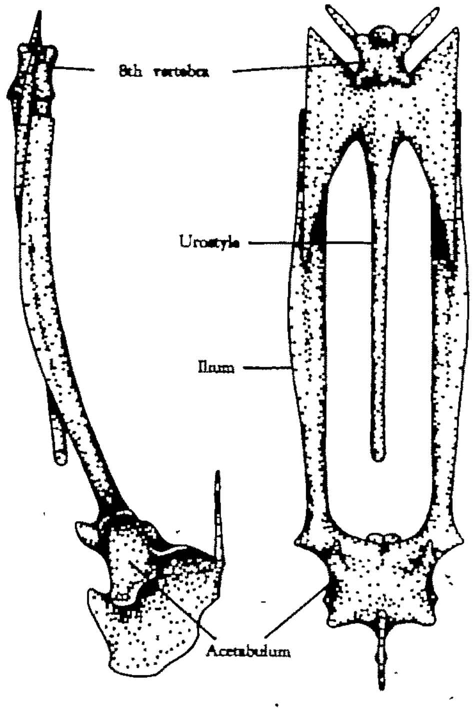

Fig. 1. Girdle and vertebral column to show the sliding articulation. *a*, from the lateral side; *b*, from the dorsal side

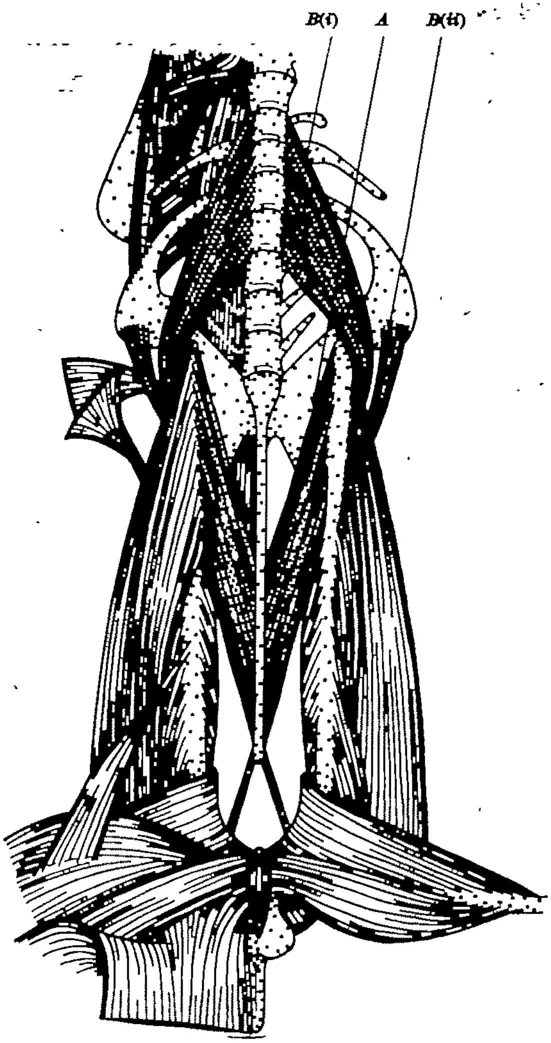

Fig. 2. Girdle and vertebral column from the ventral side with relevant muscles emphasized

In *Xenopus*, the whole propulsive effort in swimming and in burrowing occurs in one plane. The forward thrust of the hind-limbs must be transmitted through the coccygeo-iliac muscles. These muscles, together with their antagonists, will provide an effective shock-absorbing mechanism and assist in drawing the hind-limbs forward into the mud during under-water burrowing.

This work was done in the Department of Zoology of the University of Bristol. I am grateful for valuable assistance from Prof. J. E. Harris and Dr. H. P. Whiting.

Use of Collagenase in the Characterization of Pseudocoelomic Membranes of *Ascaris lumbricoides*

THE longitudinal muscle cells of *Ascaris lumbricoides* are enclosed in sheaths that form part of the system of pseudocoelomic membranes covering the internal organs of nematodes. The nature of these membranes is obscure, though Monné[1] demonstrated that they stain like collagen. Collagenous structures previously described in *Ascaris* are the cuticle and the basal lamella of the intestine. The collagenous nature of the former was inferred from the results of X-ray studies[2] and paper chromatographic analysis[3], that of the latter from X-ray studies only[4]. Neither material showed any trace of a banded structure in electron micrographs, nor did X-ray diffraction photographs suggest the presence of long spacings.

As the membranes are difficult to isolate in bulk for physical and chemical analysis, it was decided to test for the presence of collagen by using collagenase. Doubts have been expressed about the specificity of the collagenases present in *Clostridium welchii* and *C. histolyticum* filtrates, but Seifter *et al.*[5] have shown that the purified collagenase of *C. histolyticum* degrades only collagen and gelatin. Robb-Smith[6], working with mammalian tissues, showed the specificity of *C. welchii* collagenase under defined conditions, particularly when antisera are used to neutralize other enzymes present in the filtrate. As *C. histolyticum* collagenase was unobtainable, it was decided to follow the technique of Robb-Smith.

Enzyme tests were carried out using a Wellcome Physiological Research Laboratory *C. welchii* filtrate (*B* 637 *C*) with the following specifications: collagenase, 52 *k* units/mgm. (22 *Q* units/mgm.); lecithinase, 4·3 units/mgm.; protein, N 3·6 per cent; hyaluronidase, 8 units/mgm., and a small quantity of λ, a protease of unspecified concentration. A refined antiserum (*RX* 5755/36) of the following concentrations was also supplied: anti-collagenase, 1·5 units/ml.; anti-lecithinase, 220 units/ml.; anti-hyaluronidase, 650 units/ml.; anti-λ, 6,000 units/ml., which should be sufficient to neutralize the λ in *B* 637 *C*.

A solution containing approximately 1,560 *k* units (660 *Q* units) of collagenase was obtained by adding 30 mgm. of *B* 637 *C* to 1·5 ml. of *RX* 5755/36 in 100 ml. of Palitisch's[7] borate buffer at *p*H 6·8. Material was fixed in Carnoy's fluid, and paraffin sections were cut at 10μ. After the removal of paraffin, and hydration, the slides were incubated at 37° C. either in collagenase solution or in buffer solution as control. At intervals, slides were removed, washed, 'Celloidinized', and stained by the Gomori[8] modification of the Bielschowsky-Maresch silver method for collagen.

After 6 and 10 hr., the material appeared unchanged; but 12 hr. and longer incubation caused digestion not only of the basal lamella of the intestine but also of the sheaths surrounding the muscle cells. After 16 hr. incubation, the cuticle had completely disappeared apart from the external cortical layer. Bird[9] has presented evidence that this layer is a tanned protein, so its resistance is not surprising. Digestion of the basal lamella of the intestine and the internal portion of the cuticle, as well as of the sheaths surrounding the muscle cells, strongly suggests that the sheaths are collagenous.

Studies with the electron microscope are envisaged for the future.

Now that the specificity of the collagenases of clostridial filtrates has been established[5,6], its use could conveniently form a diagnostic test for collagenous materials.

I wish to thank Prof. C. F. A. Pantin for supervising this work and the Wellcome Physiological Research Laboratory for the gift of collagenase and antiserum. The investigation was undertaken during the tenure of an Agricultural Research Council Studentship.

Isolation of a Phytoalexin from *Pisum sativum* L.

THE presence of an antifungal 'principle (or principles)' produced by pods of *Phaseolus vulgaris* L. in response to infections with *Sclerotinia fructicola* (Wint.) Rhem. has been demonstrated on the basis of biological assays by Muller[1,2]. We now report the isolation of an antifungal compound produced in similar hypersensitivity studies using pods of *Pisum sativum* L., and describe some of its chemical, physical and biological properties.

The biological conditions provided for the interaction of host and fungus were similar to those reported by Muller[1], namely, the inoculation of the endocarps of detached, opened pods with a fungal spore suspension and the recovery of the drops of liquid ('diffusate') remaining on the tissue after suitable incubation periods. Quantitative bioassays, based on the inhibition of spore-germination in seeded agar blocks, with *S. fructicola* as test organism, were used to determine antifungal activity.

The active material was extracted from the crude diffusate by light petroleum (b.p. 55–60° C.); the residue was not antifungal. When concentrated extracts were fractionated using paper chromatography (solvent *n*-propanol/water, 20 : 80 v/v), the fraction with an R_F 0·6–0·7 contained most of the biological activity. An antifungal compound from this fraction has been obtained since in crystalline form by repeated re-crystallization from light petroleum. It is sparingly soluble in water but is soluble in a wide range of organic solvents. Microanalyses and molecular weight determinations are consistent with the formula $C_{17}H_{14-16}O_6$. Other physical properties include m.p. 61° C.; ultra-violet absorption maxima in water at 307 mμ (log ε 3·85) and 286 mμ (log ε 3·7); molecular optical rotation $[M^{20}_{589\,m\mu}] = 880$ ($c. = 0{\cdot}1$ in ethanol). The substance is stable in alkaline or neutral solution, but in acid solution it loses a molecule of water and becomes optically inactive and almost insoluble in water. The ultra-violet absorption maxima are displaced towards the visible and intensified, $\lambda_{max.}$ 358 mμ (log ε 4·5) and 342 mμ (log ε 4·5), in ethanol. The infra-red spectrum of the new substance confirms the loss of the hydroxyl grouping. The active material is not phenolic, nor does it contain other acidic groups.

We consider that this compound is an example of the biologically active class of compounds defined by Muller[3] as 'phytoalexins'. We propose that the trivial name of this compound should be 'pisatin' after the host plant from which it was originally isolated. *S. fructicola* was the main fungus used in this work; however, the same antifungal compound was identified in the diffusates on pea pods after inoculation with a random selection of both facultative (*Ascochyta pisi* Lib., *Cladosporium* sp., *Phoma lingam* (Tode ex Fr.) Desm., and *Septoria apii* (Briosi and Cav.)) and obligate (*Erisyphe cichoracearum* D.C., *Peronospora tabacina* Adam. and *Uromyces fabae* Pers.) plant pathogens. On our evidence the fungus used, although necessary to promote the formation of the antifungal compound, does not appear to play any specific part in determining the nature of the substance.

The median effective dose (*ED*50) of pisatin required to inhibit *S. fructicola* was around 10^{-4} *M*. The concentration for complete inhibition of this fungus was $2 \cdot 8 \times 10^{-4}$ *M*. Several washings with sterile water of spores, treated with pisatin at $2 \cdot 8 \times 10^{-4}$ *M* for 48 hr., followed by further incubation in water, resulted in part-germination, indicating that the action of pisatin was, however, only fungistatic at this concentration.

Spectroscopic and chromatographic analysis of diffusates from inoculation comparisons using a pathogen (*A. pisi*) and a non-pathogen (*S. fructicola*) of peas showed that pisatin was produced in both cases at similar concentrations. Sensitivity tests of these two fungi towards pisatin *in vitro* showed, however, that a concentration ($2 \cdot 8 \times 10^{-4}$ *M*) of this compound which completely inhibited germination of *S. fructicola* inhibited germination of *A. pisi* by only 25 per cent under the same conditions.

Detached pods have normally been used in our tests; however, pisatin has been detected at a concentration adequate to inhibit completely germination of *S. fructicola* in pods inoculated on growing plants with this fungus. Pisatin has also been detected in pods naturally infected with *A. pisi* under field conditions.

Extracts prepared from *Phaseolus vulgaris* and *Capsicum frutescens* L. under similar inoculation conditions to those described in the earlier sections of this communication show antifungal activity comparable with extracts from *Pisum sativum*, and the effective substances can be extracted into light petroleum. However, the spectrophotometric evidence shows that pisatin is not the antifungal substance in the other host plants. This may indicate a degree of host specificity for this biological class of compounds.

Flor[4] postulated a gene-for-gene relationship in host/pathogen systems. It is suggested that the situation required for a resistant reaction, namely, a host in which infection stimulates the production of a phytoalexin at a concentration above the threshold which inhibits the fungus, is consistent with this hypothesis.

The interest of Dr. W. Bottomley is gratefully acknowledged.

A full account of this work will be published elsewhere.

BACTERIOLOGY

Transformation of Resistance to 8-Azaguanine in *Diplococcus pneumoniae*

Because of the importance of purine analogues in the chemotherapy of human neoplastic disease[1], several investigations have been made on their mode of action and the mechanism of resistance[2] to them in bacterial and animal systems.

We describe here the induction of resistance to 8-azaguanine in *Diplococcus pneumoniae* by means of a transformation mediated by deoxyribonucleate. This suggests that the acquisition of resistance to this antimetabolite, like many other inhibitors, occurs by an alteration of the genetic substance in cells normally sensitive to the drug and provides a means for genetic manipulation, already shown to be unique in its advantages for investigations of gene-controlled resistance mechanisms.

Strains resistant to 8-azaguanine were obtained by isolation of single cells from cultures of a rough variant of *D. pneumoniae* serially transferred in purine-free medium containing increasing concentrations of drug. The growth medium (Table 1) was that of Adams and Roe[3], modified by replacing acid-hydrolysed casein with enzymatically digested casein; adding sodium acetate; decreasing the concentrations of cystine, glutamine, asparagine, choline, calcium chloride, and dipotassium hydrogen phosphate; and omitting tryptophan, adenine, uracil, and potassium chloride. By the addition of small amounts of specific agglutinating rabbit serum, growth, following the dilution of culture material in this medium, occurred in the form of distinct colonies on the bottom of the culture tube. The

enumeration of colonies in this medium made selective by the addition of drug formed the basis of our quantitative procedure[4].

Deoxyribonucleic acid was prepared from cultures of resistant cells lysed by deoxycholate using the 'Duponol' deproteinization method of Kay *et al.*[5]. After growth of the drug-susceptible parent strain at 37° C. for a period of 2–3 hr. in the casein hydrolysate medium supplemented with 0·16 per cent bovine albumin (Armour fraction V), deoxyribonucleic acid was added and the culture re-incubated for 2 hr. at 37° C. to allow for adequate genetic expression. The results of typical experiments with deoxyribonucleic acid extracted from a strain of *D. pneumoniae* [*R6/AZAG*(1)] resistant to 0·5 μgm./ml. 8-azaguanine (a 100-fold increase in resistance over that exhibited by the parent strain) are shown in Table 2.

The presence of drug-resistant organisms was determined by diluting aliquots of the culture which had been exposed to deoxyribonucleic acid in the purine-free anti-serum medium containing 0·5 μgm./ml. 8-azaguanine. After incubation at 37° C., resistant colonies were observed, with the number depending on the concentration of deoxyribonucleic acid. These colonies were assumed to arise from individual transformants induced by deoxyribonucleic acid, since none was obtained from parallel cultures which were: (*a*) not exposed to deoxyribonucleic acid, (*b*) exposed to deoxyribonucleic acid pretreated with deoxyribonuclease (in 0·002 *M* magnesium chloride), or (*c*) exposed to deoxyribonucleic acid isolated from a parent strain susceptible to 8-azaguanine.

It was later determined that after addition of deoxyribonucleic acid only a brief period of incubation at 37° C. (about 10 min.) was required before the transformed cells could be exposed to selective concentrations of 8-azaguanine. This was not due to a rapid phenotypic expression of the newly transformed character but to the inability of 8-azaguanine to inhibit drug-sensitive cells immediately.

All the transformants obtained with deoxyribonucleic acid extracted from strain *R6/AZAG*(1) displayed a level of resistance equal to that of the original donor strain (first transformation, Table 3). On the other hand, deoxyribonucleic acid from another mutant strain [*R6/AZAG*(2)], resistant to 5·0 μgm./ml. 8-azaguanine, induced more than one class of transformants. Following dilution of cultures exposed to deoxyribonucleic acid in antiserum medium containing varying drug concentrations, the majority of transformants were found to be resistant to either 0·5 or 0·8 μgm./ml. 8-azaguanine, while only a few transformants were resistant to the same level as the original donor strain. In other transformations (second transformation, Table 3), transformants derived from *R6/AZAG*(1) and low-level transformants from *R6/AZAG*(2) all transmitted their markers intact. When high-level transformants from *R6/AZAG*(2) were used as donors of deoxyribonucleic acid, the same three classes of transformants that were derived from the original donor strain were again obtained. Strain *R6/AZAG*(1) appears to bear only a single genetic marker for 8-azaguanine resistance. The results obtained with the other donor strain, *R6/AZAG*(2), indicate a dissemination during transformation of two genetic markers in its deoxyribonucleic acid. The high-resistance level transformants would be expected to occur with lower frequency since the simultaneous addition of both markers to the genome of the recipient cell would be required.

Table 3

Donor Strain	Donor Resistance level (μgm./ml.)	Transformants Resistance level (μgm./ml.) First transformation	Second transformation
R6	0·005	—	—
R6/AZAG(1)	0·5	0·5	0·5
R6/AZAG(2)	5·0	0·5	0·5
		0·8	0·8
		5·0	0·5
			0·8
			5·0

It appears that resistance to 8-azaguanine, in this organism at least, originates by more than one genetic alteration, and that the development of a specific level of resistance to the drug, like resistance to other agents, may occur in increments (stepwise) following the addition by successive mutations of additional genetic markers.

Absence of Carbon Monoxide-sensitive Respiration in a Streptomycin-dependent Mutant of *Escherichia coli* grown in Limited Amount of Streptomycin

Miller and Bohnhoff[1] were the first to report the existence of streptomycin-dependent micro-organisms. Since then various species of bacteria have been found to give rise to streptomycin-dependent mutants[2–4].

The problem of streptomycin-dependency has been studied very little and at present is still unsolved.

Schaeffer[5] found a decrease in cytochrome content in a streptomycin-dependent mutant of *Bacillus cereus* when deprived of streptomycin. Since under similar conditions the cytochromes of a streptomycin-dependent mutant of *Escherichia coli* were unaffected, he concluded that although streptomycin may be necessary for the mutant strain of *B. cereus* to synthesize cytochromes, its role in streptomycin-dependent mutants of other species may be of a different nature.

This communication constitutes a preliminary report of our work on electron transport systems of streptomycin-dependent bacteria.

Escherichia coli Sd-4, a streptomycin-dependent mutant, was used. The cells were grown on the surface of Roux bottles in the synthetic medium of Davis[6], supplemented with streptomycin. For optimal and suboptimal growth 100 and 1 μgm. of streptomycin per 1 ml. of medium were added, respectively. For the preparation of non-proliferating suspensions an 18-hr. old culture was employed. Experiments on oxygen uptake were carried out by the conventional method in Warburg apparatus. The filling of vessels with the various carbon monoxide–oxygen mixtures was done by the evacuation method of Umbreit[7].

Our experiments have shown that in the presence of all the substrates tested (glucose, pyruvate, lactate, malate, succinate, α-ketoglutarate, acetate, glutamate and serine) the rate of respiration of the non-proliferating cells grown in sub-optimal amount of streptomycin was markedly lower than that of cells grown under optimal conditions. Experiments on the effect of carbon monoxide on the respiration of the aforementioned cells showed that the bacteria grown in a limited amount of streptomycin, in contrast to those grown under optimal conditions, lacked the carbon monoxide-sensitive pathway of respiration.

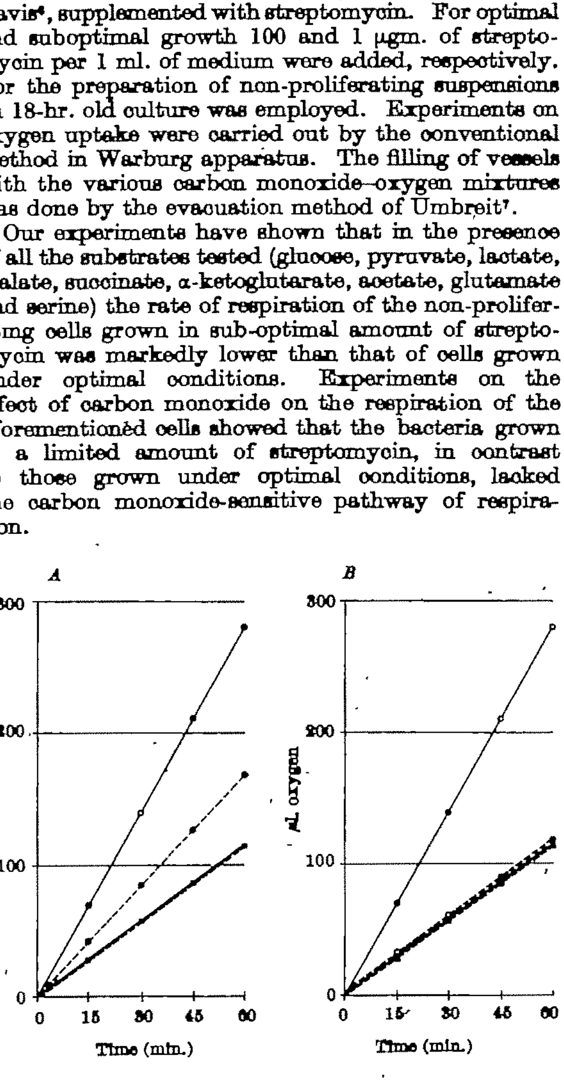

Fig. 1. Effect of carbon monoxide on respiration of non-proliferating cells of a streptomycin-dependent mutant of *E. coli* grown in optimal and suboptimal amounts of streptomycin. Each Warburg flask contained: 0·125 mgm. *N* bacterial suspension, 0·5 ml.; 0·1 *M* phosphate buffer *p*H 7·0, 0·5 ml.; 0·2 *M* sodium lactate, 0·3 ml. (in the side bulb, tipped after 15 min. of equilibration); 15 per cent potassium hydroxide, 0·2 ml. in the centre well; the final volume was 2·2 ml. made up with distilled water. The temperature of the water-bath was 37° C. *A*, Ratio of oxygen : carbon monoxide = 0·1; *B*, ratio of oxygen : carbon monoxide = 0·05, continuous line, controls without carbon monoxide; broken line, with carbon monoxide; ○, cells grown in the presence of 100 μgm. of streptomycin per 1 ml. of medium; ■, cells grown in the presence of 1 μgm. of streptomycin per 1 ml. of medium

A typical experiment on respiration of cells grown in limited and unlimited amount of streptomycin and the effect of carbon monoxide on their oxygen uptake is shown in Fig. 1. It can be seen from the curves in the figure that, in the presence of lactate, the $Q_{O_2}^{N}$ of the optimally grown cells is 2,240 as compared to 920 of the cells grown with limited streptomycin. Carbon monoxide inhibits only the respiration of optimally grown cells, and is completely without effect on the respiration of the suboptimally grown ones. At a ratio of oxygen : carbon monoxide equal to 0·1 the inhibition of the total oxygen uptake by cells grown under optimal conditions is about 40 per cent while the respiration of cells grown in limited amount of streptomycin is unaffected. On lowering the ratio of oxygen : carbon monoxide to 0·05 the inhibition of respiration of the former increases, reaching 60 per cent, whereas the respiration of the latter remains unimpaired. As a result the rate of respiration of both kinds of cells becomes equal.

We may, therefore, conclude that the low rate of respiration displayed by bacteria grown with limited streptomycin is brought about by cytochrome oxidase, being either absent or non-functional.

Full results and discussion of the above findings in relation to streptomycin dependency will be reported at a later date.

We are indebted to Dr. Demerec for his gift of the *E. coli Sd-4* strain. This is a preliminary report on an investigation carried out by one of us (H. E.) in partial fulfilment of the requirements for the Ph.D. degree of the Hebrew University—Hadassah Medical School.

A Bacterial Mutant with Impaired Potassium Transport

THE transport of substances across cell membranes against electrochemical potential gradients is attributed to the operation of energy-dependent pumps in the cell membrane. However, the exact chemical nature of these pumps and their link to metabolic energy sources remain unknown. The purpose of the present communication is to report the isolation of a genetic variant of the bacterium *Escherichia coli* (strain *K*-12) which differs from the original strain (prototroph) with respect to the accumulation and metabolism of intracellular potassium. (Since this communication was submitted, M. Lubin and D. Kessel, *Biochem. and Biophys. Res. Comm.*, 2, 249 (1960), have discussed a similar topic.) Preliminary evidence demonstrates that, whereas the prototroph transports potassium into the cell with a half-time of 3½ min., the potassium mutant transports potassium at a rate so slow as to be scarcely detectable.

The potassium mutant, called Φ_{K}-, was isolated by means of the penicillin method described by Davis[1,2] and Lederberg and Zinder[3], with some modifications similar to those recently described by Gorini and Kaufman[4]. 10 ml. of *E. coli* growing exponentially in a minimal medium containing 1 per cent glucose[5] were exposed to a pre-calibrated dose of ultra-violet radiation calculated to reduce the viable count to approximately 0·1 per cent of the initial population size. Following a 12–24 hr. intermediate cultivation in an enriched medium ('Nutrient Broth', Difco), a 10 ml. sample was centrifuged and the pellet washed three times with cold potassium-free buffer solution (identical with the minimal medium[5] except for a mole for mole substitution of sodium for potassium). Approximately 0·1 ml. of the resuspended pellet was inoculated into 50 ml. of nutrient broth which had been twice passed through an ion exchange resin column ('Dowex 50'). This procedure resulted in the replacement of 99·96 per cent of the potassium initially present with sodium, reducing the concentration of potassium from 24 m*M* to 0·01–0·03 m*M*. The inoculum was then shaken for 6–8 hr. at 37° C. until a stationary phase was reached as was to be expected when intracellular potassium reserves had been depleted. Crystalline sodium penicillin (Nutritional Biochemical) was added to give a final concentration of 10,000 units/ml. In addition, potassium dihydrogen phosphate was added to raise the concentration of potassium in the broth to 1 m*M*. Previous studies had shown that the *E. coli* prototroph will grow normally at this extracellular potassium concentration, accumulating potassium against a more than 100-fold concentration gradient. If a mutant incapable of concentrating potassium were present, it alone should be incapable of growth in this enriched, potassium-poor medium, thus escaping the bactericidal action of penicillin on growing cells. A large volume of broth was used in this step to minimize increase in extracellular potassium following lysis of the potassium-rich cells.

Following 8–10 hr. of incubation at 37° C., the culture was centrifuged. 0·1 ml. of resuspended precipitate was spread on potassium-rich agar plates (broth, potassium > 24 m*M*), which were then incubated at 37° C. When growth had resulted in colonies 1–2 mm. in diameter, replicas were made on potassium-poor plates (broth, potassium < 1 m*M*). A single colony grew on the potassium-rich plate but failed to grow on the potassium-poor plate. The control prototroph grew equally well on both plates. Two repeated platings on potassium-rich and potassium-poor minimal agar plates revealed the same differential growth pattern, ruling out the possibility that the auxotroph required a nutrient which was inadvertently removed by the ion exchange resin.

A series of experiments was then performed to compare the effect of potassium concentration on growth of prototroph and Φ_K- in minimal liquid media containing 1 per cent glucose. Unexpectedly, the growth of Φ_K- now appeared to be independent of external potassium from 0·1 to 10^{-5} *M* ; Φ_K- growth exceeded that of the prototroph below 10^{-3} *M* potassium. This result indicated that the organism originally isolated, Φ_K-, had become adapted to growth in the presence of potassium too low to permit normal growth of the prototroph. Furthermore, determinations of intracellular potassium in both prototroph and Φ_K- grown to the stationary phase in liquid media of varying concentrations of potassium revealed striking differences. As shown in Fig. 1, the prototroph maintained its internal potassium at 115–125 m.equiv./(l. cell water) in a 10^{-5} *M* medium, whereas Φ_K- was characterized by significantly lower intracellular potassium.

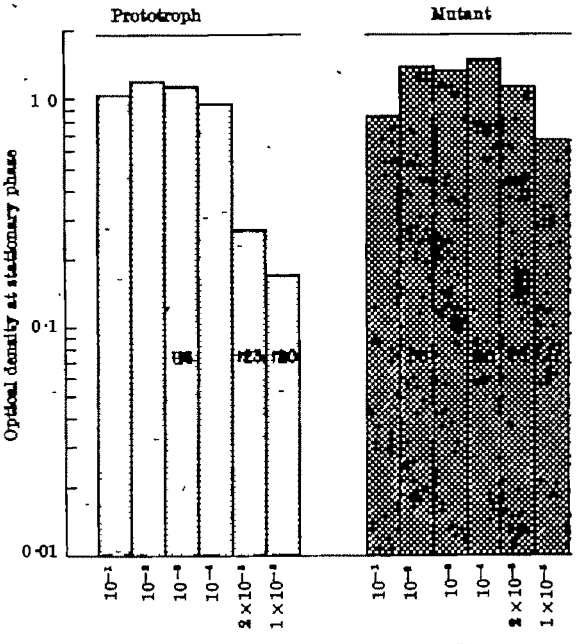

Fig. 1. The relative growth of the *E. coli* prototroph and mutant in media with varying concentrations of potassium as measured by the stationary phase optical density at 550 mμ. The figures in the bars represent the intracellular potassium concentrations in m.equiv./(l. cell water)

Potassium-42 was used to study the potassium fluxes in prototroph and auxotroph suspensions in potassium-poor minimal media. Fig. 2 shows the time-course of disappearance of potassium-42 from the extracellular phase in a suspension of freshly grown cells. Normal cells (1·6 mgm. dry wt./ml. suspension ; medium potassium = 1·25 m*M*) take up potassium-42 avidly, as shown in the lower curve. An initial rapid phase is followed by a slower phase characterized by a half-time of 3¼ min. The points represent experimental results and the curve for the slower phase has been drawn according to two-compartment kinetics with an efflux transfer coefficient of 0·16/min. Since the cells were in the early lag phase, cell growth was negligible during the 12-min. kinetic study, as demonstrated by the observation that the fractional

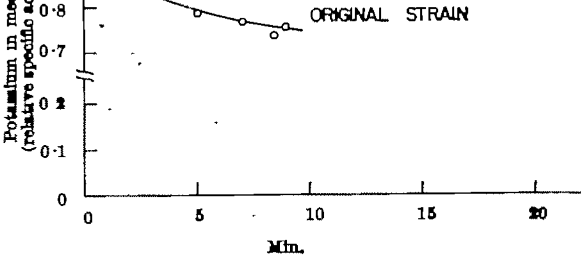

Fig. 2. Potassium-42 influx into the prototroph and mutant. It can be seen that the original strain takes up potassium-42 much more rapidly than the mutant. The points represent experimental data and the curves have been drawn as described in the text

volume of cells in the medium increased less than 5 per cent during this period.

On the other hand, the mutant (2·1 mgm. dry wt./ml. suspension ; medium potassium = 2·5 mM) takes up potassium very slowly. The dashed line in Fig. 2 has been drawn for a linear uptake of 4·5 per cent in 10 min. After 135 min., the specific activity of the auxotroph is 0·3 that of the medium, which is consistent with a slow rate of uptake of potassium-42. Since the mutant was present in a more concentrated suspension and exposed to a higher extracellular potassium concentration than the prototroph, the true difference in their rate of uptake of potassium-42 is probably greater than our present estimate. As our studies indicate that growth of Φ_K- can be maintained in a potassium-poor minimal medium, it may be inferred that the lesion in potassium transport resides either in the transport system or in its energy supply.

In summary, our preliminary studies suggest that the Φ_K- auxotroph we have isolated differs from the prototroph of *Escherichia coli* in two respects. First, its ability to accumulate potassium against a concentration gradient is greatly impaired. Secondly, the auxotroph has the capacity to adjust itself to a potassium-deficient environment. This Φ_K- mutant would appear to offer promise as a tool to investigate both the nature of the potassium transport mechanism and the role of potassium in intracellular metabolism.

This work has been supported in part by the National Science Foundation and by the Atomic Energy Commission.

We are grateful to Dr. B. D. Davis for his discussion in the early phases of the project and his assistance in the development of the technique, and to Mr. A. F. Hurley for his incisive and helpful comments.

GENETICS

Mechanisms of Meiotic Non-disjunction in Man

IT is now well known that there is an abnormal chromosome number in mongolism in chromatin-positive Klinefelter's syndrome, and in chromatin-negative Turner's syndrome. It is also known that mongolism is associated with increased maternal age, and there is some evidence that a similar association exists in chromatin-positive Klinefelter's syndrome[1,2] and in chromatin-negative Turner's syndrome[1]. In cases of chromatin-positive Klinefelter's syndrome previously studied the available data (Table 1) provide supporting evidence that there is an association with, among other possibilities, increased maternal age. Fifty-four cases were classified with respect to position in the sibship. Four were in the centre of the sibship and of the remaining 50 cases, 17 were in the first half and 33 in the second half. This is significantly different from the expected 25 to 25 distribution.

Table 1. POSITION OF PATIENT IN SIBSHIP

		1	2	3	4	5	6	7	8	9	10	11	12	13	
Number in sibship	1	3													3
	2	3	10												13
	3	0	1	8											9
	4	1	2	0	2										5
	5	0	1	0	1	5									7
	6	1	0	1	1	0	1								4
	7	0	0	0	0	0	0	2							2
	8	0	0	0	1	0	0	0	1						2
	9	1	0	0	0	0	0	0	1	0					2
	10	0	0	1	0	0	0	0	0	1	3				5
	11	0	0	0	0	0	0	0	0	0	0	1			1
	12	0	0	0	0	0	0	0	0	0	0	0	0		0
	13	0	1	0	0	0	0	0	0	0	0	0	0	0	1
		9	15	10	5	5	1	2	2	1	3	1	0	0	54

It is generally agreed that meiotic non-disjunction is the most probable cause of these conditions. Further information about the number and origin of X chromosomes can be obtained from colour-blindness studies[3-5]. A colour-blind chromatin-positive case of Klinefelter's syndrome with colour-normal parents could be due to a defect of oogenesis. This was pointed out independently by Stewart[3] and Stern[4]. Stern considers that available data on chromatin-positive Klinefelter's syndrome suggest an abnormality of the first meiotic division but they are, in fact, equally consistent with a defect of the second meiotic division. The expected frequency of colour-blindness following a second meiotic abnormality which he quotes (8 per cent) is correct for a locus close to the centromere but he does not consider the expected frequency for a locus sufficiently far from the centromere to give random segregation. The frequency of females homozygous for colour-blindness is 0·5 per cent. All XX eggs from such individuals will be homozygous recessive for colour-blindness. The frequency of females heterozygous for colour-blindness is 15 per cent and with random segregation one-sixth of their secondary oocytes will carry the gene for colour-blindness on both chromatids. Non-disjunction at the second meiotic division gives exceptional XX eggs and 2·5 per cent of these will be homozygous recessive (one-sixth × 15 per cent). The expected frequency of colour-blindness in exceptional individuals due to a second meiotic abnormality is therefore 3 per cent (2·5 per cent from heterozygous mothers and 0·5 per cent from homozygous mothers). Thus the expected limits of colour-blindness incidence in exceptional individuals following an abnormality of the second meiotic division of oogenesis are 3–8 per cent. Collection of further data may provide information about the position of the colour-blindness locus relative to the centromere, about the relative frequency of non-disjunction in oogenesis and spermatogenesis and about the state of meiosis at which non-disjunction occurs[5].

There is good evidence that some cases of chromatin-negative Turner's syndrome are due to a defect of spermatogenesis and that some cases of chromatin-positive Klinefelter's syndrome are due to a defect of oogenesis ; and the opposite situations probably occur[5]. A defect of oogenesis may be assumed if a colour-normal case of chromatin-negative Turner's syndrome is found with a colour-blind mother and a colour-normal father, and a defect of spermatogenesis would be indicated by a colour-normal case of chromatin-positive Klinefelter's syndrome with a colour-blind mother and a colour-normal father[6]. Defects of spermatogenesis in the chromosomal intersexes may be related to the unequal size of the X and Y chromosomes with consequent failure of pairing leading to non-disjunction during meiosis. In oogenesis all chromosomes are paired, but a similar causal mechanism might operate for a chromosomal aberration such as inversion could lead to failure of pairing and non-disjunction. A chromosomal aberration of this sort might be inherited or it might be caused by environmental influences. A possible clue to the mechanism is provided in the reports that mongolism is associated with increased maternal age but not with increased paternal age[1], and that there is little increase in the number of female germ cells after birth[7]. Environmental influences, including temperature, hormones and those such as radiation which cause genetic change, may predispose to defects of oogenesis but not to defects of spermatogenesis if old women have old eggs but old men have young sperm.

[7] Zukerman, S., Ciba Colloquium on Ageing, 2, 31 (1956).

IT is useful at this stage of human cytogenetics to keep in mind the whole spectrum of possibilities of chromosomal behaviour. In this sense Dr. Stewart's emphasis on the possibility of non-disjunction during the second meiotic division is valuable. His discussion rests on the assumption that non-disjunction is preceded by crossing-over between homologous chromosomes. In my discussion of second division non-disjunction I had specified absence of crossing-over (and, thus, made no assumption as to closeness of the locus for colour blindness to the kinetochore). According to Dr. Stewart's scheme it would follow that genes distantly located would less often become homozygous than proximal genes. This is the opposite to what is well established in *Drosophila*, although it cannot be excluded, of course, that human chromosomes may behave differently. In *Drosophila* the more frequent homozygosis for distal than proximal genes signifies that non-disjunction preceded by crossing-over occurs during the first meiotic division.

Apart from the question whether non-disjunction occurs during the first or second meiotic division, Ford's suggestion that it may also occur in early cleavage cannot be dismissed[1]. This suggestion accounts for homozygosis of the locus for colour-blindness by mitotic non-disjunction without reference to crossing-over or of gene location.

I wish to add two minor points in reference to my earlier communication: (1) The statement about a 'maximum' of recessive homozygosis of 16·7 per cent was in error; instead this frequency follows from random assortment. (2) The choice of 0·5 per cent as the incidence of colour-blind women was made for the sake of a round number; 0·45 or 0·4 per cent are more accurate values.

Effect of Variations in Temperature on Meiosis in *Gagea reticulata* Schultes

PREVIOUS cytological investigations on the genus *Gagea* have been confined to eight species[1]. Recently, Malik and Sehgal[2] contributed to the cytology of one more species, *Gagea reticulata* Schultes. The haploid chromosome number determined was twelve. The meiotic behaviour of chromosomes, as seen from the dividing pollen mother cells, was regular in plants growing in their normal season (February). The pairing of the chromosomes was perfectly normal, followed by regular anaphasic separations, and resulted in a high degree of fertility.

A few plants of *G. reticulata* were collected from the same locality growing late in the season (May). A number of meiotic irregularities were recorded in these individuals. These comprised non-pairing of chromosomes, early disjunction, the presence of bridges and laggards with unequal distribution of chromosomes at anaphases. As a result of all these irregularities, quantitatively equal or unequal tetrads, pentads and even configurations above this level were formed. Pollen-grains thus formed were extremely variable in size.

These meiotic irregularities could not be due to the fixative, for in both cases this was kept constant.

Several workers have artificially induced many meiotic abnormalities such as desynapsis, stickiness, laggardism and formation of diploid spores. Sax[3] has described such meiotic aberrations after subjection to various temperatures in *Tradescantia paludosa*. Similar effects of temperature on pollen formation and meiosis in *Hieracium robustum* have been reported by Gustafsson and Nygren[4]. Such chromosomal irregularities are also reported to be caused by various environmental conditions. Matsuura and Haga[5] reported that normal meiosis occurred in *Trillium kamtschaticum* during winter. When these plants were grown in warmer temperatures, they showed a breakdown in meiosis. The course of meiosis was normal in buds of *G. reticulata* plants collected in February. The abnormalities described above were from plants collected in May and apparently due to the reaction of the plant to its environmental factors. Since these aberrations were observed in the hot months of May, it is reasonable to assume that the extreme heat could be responsible for the disturbances in meiosis. In this connexion, it is pertinent to compare the average maximum temperature in these months in the same locality, which during February was 18° C. and in May 38° C. It is tempting to suggest that the course of meiosis in flowers of plants in May was modified by high temperature to which the plant is ordinarily not adapted; and ever since the observations of Malik and Tandon[6,7] on *Asparagus curillus* Ham. and *Suaeda fruticosa* Forsk., it has become increasingly clear that there is a correlation between temperature and meiotic course. Khoshoo[8] has also reported a similar situation in *Sisymbrium irio*, in which meiotic disturbances were caused by summer heat.

A detailed account of these investigations will be published elsewhere.

I am indebted to the principal of this College, Dr. A. N. Banerji, for providing the necessary facilities in connexion with the present investigations.

Race Differences in the Ability to excrete Beetroot Pigment (Betanin)

IT has been suggested that lack of betanin excretion in urine is a hereditary trait in man[1]. This could result from an inborn incapacity to metabolize the pigment. This communication reports a study of the frequencies of betanin excretors among different racial groups. Classification of the excretors necessitated taking into account the time-range necessary for excretion, the amount of beetroot eaten and the *p*H of the urine. The effect of these variables on the validity of the test was determined before establishing the following procedure. 100–150 gm. of cooked beetroot was given to each individual examined. Two test-tube samples were taken, one before and the other 5 hr. after the beetroot was eaten. The classification of the individuals as excretors and non-excretors was based on visual comparison of the colour of the two urine samples. When any reddish tint could be observed in the second sample relative to the first the subject was recorded as 'excretor', and if otherwise, 'non-excretor'. It should be noted that a great deal of variation was observed in the intensity of the red tint in the urine of the excretors.

As betanin is a *p*H indicator, the possibility that a high *p*H in the urine could suppress the appearance of the colour was checked. It was found that lowering the *p*H near 5 in the urine of the 'non-excretor' group failed to reveal any reddish tint. On the other hand, an increase of *p*H to 8 in the 'excretor' group was needed to make the tint fade. Since human urine has a *p*H varying between 4·8 and 8·2 (average, 6) it can be concluded that the *p*H value of the urine does not appreciably affect the results.

It was observed that betanin elimination by the adult excretors occurs 4–11 hr. after eating beetroot, the most intense concentration of the pigment in urine being about 5–6 hr. after ingestion. Among children 8–14 years old, the corresponding time is 3–4 hr.

A group of 338 individuals from São Paulo was examined in State schools for resident pupils, where the tests could be controlled. The investigation includes 181 Japanese of age-range between 7 and 24 years, 50 Negroes 'pure' and 'mixed' of age-range between 20 and 46 years and 107 Whites of age-range between 13 and 53 years. The frequencies of excretors in the three samples are given in Table 1.

Table 1

Sample	Mean age	No. of individuals examined	Excretors No.	Excretors Per cent
Japanese	14·6	181	80	44·2
Negro	31·9	50	16	32·0
White	23·0	107	33	30·8
Total	19·4	338	129	38·2

Heterogeneity, $\chi^2_{(2)} = 6{\cdot}13$, $P < 0{\cdot}05$.

It should be noted that the frequencies of excretors among two different samples of Japanese taken at random were 47·6 per cent ($n = 103$) and 45·3 per cent ($n = 64$). The frequency of excretors among Whites from São Paulo, who came from different European immigrant groups, is higher than that observed for the English group (10 per cent)[1]. This fact is likely to be caused by the heterogeneous origin of our White sample (mainly of Italian and Portuguese derivation) and/or by differences in technique. The difference in frequencies of excretors between the White and the Negro samples ($\chi^2_{(1)} = 0{\cdot}02$, $P > 0{\cdot}90$), or between the Negro and the Japanese samples ($\chi^2_{(1)} = 2{\cdot}40$, $P = 0{\cdot}12$) is not significant. However, the difference in frequencies of excretors between the White and the Japanese samples ($\chi^2_{(1)} = 5{\cdot}03$, $P = 0{\cdot}025$) is significant. The overall frequencies of excretors among male (41·1 per cent) and female (36·1 per cent) individuals are not significantly different ($\chi^2_{(1)} = 0{\cdot}52$, $P = 0{\cdot}53$). A group of 40 individuals of the Japanese sample has been investigated previously for taste thresholds for phenylthiourea[2], but the two traits showed no association ($\chi^2_{(1)} = 2{\cdot}43$, $P = 0{\cdot}12$).

The samples from the three ethnic groups investigated have different average ages. If betanin excretion changes with the age of the individual, this perhaps could explain the differences found. However, classifying the individuals according to the overall mean age (about 20 yr.) the results given in Table 2 were obtained.

Table 2

Sample	Age group	No. of individuals	Excretors (per cent)
Japanese	below 20 yr.	158	44·3
	20 yr. and over	23	43·5
White	below 20 yr.	34	26·5
	20 yr. and over	73	32·9

Hence, it can be seen that age variation cannot account for the differences found. Therefore, our results suggest marked differences in the frequency of betanin excretors among racial groups. Studies of this trait in other populations should be of interest.

FORTHCOMING EVENTS

Wednesday, August 31—Wednesday, September 7

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE (at Cardiff)—122nd Annual Meeting.

Wednesday, August 31

At 8 p.m.—Sir George Thompson, F.R.S: "The Two Aspects of Science" (Presidential Address).

Thursday, September 1

At 10 a.m.—Dr. James Taylor: "Chemistry is Not Enough, or the Increasing Scope of Scientists' Work in Industry" (Presidential Address, Section B).

At 10 a.m.—Dr. G. S. Carter: "Tropical Climates and Biology" (Presidential Address, Section D).

At 10 a.m.—Sir Alfred Pugsley, F.R.S.: "Statics and the Engineer" (Presidential Address, Section G).

At 10 a.m.—Prof. E. Estyn Evans: "The Peasant and the Past" (Presidential Address, Section H).

At 10 a.m.—Prof. T. M. Harris, F.R.S.: "The Origin of Angiosperms" (Presidential Address, Section K).

At 10 a.m.—Dr. William Davies: "Pastoral Systems in Relation to World Food Supplies" (Presidential Address, Section M).

At 11.15 a.m.—Mr. T. B. Peace: "The Dangerous Concept of the Natural Forest" (Chairman's Address, Section K*).

At 2.15 p.m.—Mr. A. B. Oldfield-Davies: "Science Broadcasting in Sound and Television" (Presidential Address, Section X).

Friday, September 2

At 10 a.m.—Dr. R. van der Riet Woolley, F.R.S.: "Stellar Motions" (Presidential Address, Section A).

At 10 a.m.—Prof. E. G. Bowen: "Welsh Emigration Overseas" (Presidential Address, Section E).

At 10 a.m.—Prof. R. S. Sayers: "Monetary Thought and Monetary Policy in Great Britain" (Presidential Address, Section F).

At 10 a.m.—Prof. William Burns: "The Physiology of Hearing" (Presidential Address, Section I).

At 10 a.m.—Prof. H. C. Dent: "Sixty Years of Progress in English Education" (Presidential Address, Section L).

At 11.30 a.m.—Prof. R. C. Oldfield: "Experiment in Psychology—a Centenary and an Outlook" (Presidential Address, Section J.)

At 11.30 a.m.—Dr. Michael P. Reece: "The Physical Principles of Switches and Circuit-Breakers" (Kelvin Lecture).

At 11.30 a.m.—Mr. W. M. Williams: "The Social Study of Family Farming" (Lister Lecture).

At 8 p.m.—Prof. H. Bondi, F.R.S.: "The Structure of the Universe" (Evening Discourse).

Sunday, September 4

At 11 a.m.—Service at Llandaff Cathedral. Preacher: The Bishop of Llandaff.

Monday, September 5

At 10 a.m.—Symposium on "World Food and Population". Chairmen: Sir George Thomson, F.R.S., and Sir James Gray, F.R.S. Principal Speakers: Dr. N. C. Wright, Prof. D. V. Glass, Prof. W. A. Lewis, Dr. L. Dudley Stamp, Sir Alexander Fleck, F.R.S., Dr. H. D. Kay, F.R.S., Prof. P. M. S. Blackett, F.R.S.

At 8 p.m.—Dr. E. B. Chain, F.R.S.: "Microbiological Methods in the Development of Drugs" (Evening Discourse).

Tuesday, September 6

At 10 a.m.—Mr. G. F. Mitchell: "Pleistocene History of the Irish Sea" (Presidential Address, Section C).

At 10 a.m.—Prof. D. V. Glass: "Population Growth, Fertility and Problems of Policy" (Presidential Address, Section N).

Wednesday, September 7

At 10 a.m.—Mr. Martin J. Wells: "What the Octopus Makes of it: Our World from Another Point of View" (Darwin Lecture).

Thursday, September 1

BRITISH INTERPLANETARY SOCIETY, and the SOCIETY OF INSTRUMENT TECHNOLOGY (at Manson House, 26 Portland Place, London, W.1), at 10.30 a.m.—Joint Symposium on "Rocket and Satellite Instrumentation".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

BIOLOGIST (with research experience, and preferably with Ph.D. qualification) IN THE DEPARTMENT OF ZOOLOGY, to head a small research team investigating tank culture of bivalves and marine phytoplankton—The Secretary and Registrar, The University, Southampton (August 31).

RESEARCH ASSISTANTS (3) (with, or candidates for, B.Sc. special chemistry or B.Pharm. degree of the University of London). Two posts in the CHEMISTRY DEPARTMENT, for projects in the fields of organic and physical chemistry, and one in the PHARMACY DEPARTMENT, for a project in any branch of pharmacy approved by the Head of the Department—The Registrar, Brighton Technical College, Brighton (September 3).

TEMPORARY TUTOR IN PHILOSOPHY—The Registrar, University College, Singleton Park, Swansea (September 3).

LECTURER (with a good honours degree and preferably teaching experience) IN MATHEMATICS at the Nigerian College of Arts, Science and Technology, Enugu—The Council for Overseas Colleges, 12 Lincoln's Inn Fields, London, W.C.2 (September 5).

SENIOR LECTURER IN MECHANICAL ENGINEERING at the Jamaica College of Arts, Science and Technology, Kingston—The Council for Overseas Colleges, 12 Lincoln's Inn Fields, London, W.C.2 (September 6).

SCIENTIFIC OFFICER, for research on environmental physiology of the pig—The Secretary, Institute of Animal Physiology, Babraham, Cambridge (September 9).

LECTURER or ASSISTANT LECTURER IN PHYSICS—The Registrar, The University, Sheffield (September 10).

TUTORIAL STUDENT (graduate, or about to graduate) IN THE DEPARTMENT OF GEOGRAPHY—The Registrar, King's College (University of London), Strand, London, W.C.2 (September 10).

ASSISTANT (with a degree in science, preferably honours) IN THE CHEMISTRY DEPARTMENT, West of Scotland Agricultural College, Auchincruive, Ayr, for work relating to the spectrographic analysis of agricultural materials—The Secretary, West of Scotland Agricultural College, 6 Blythswood Square, Glasgow, C.2 (September 14).

LECTURER (engineer or physicist with special qualifications to teach one or more branches of electronic engineering, and a good honours degree followed by at least three years research or industrial experience) IN THE DEPARTMENT OF ENGINEERING—The Secretary, The University, Edinburgh (September 17).

LECTURER (medical or honours science graduate) IN THE DEPARTMENT OF BACTERIOLOGY—The Secretary, The University, Edinburgh (September 17).

CHAIR OF PSYCHOLOGY in the University of Auckland, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (New Zealand and London, September 30).

LECTURER/ASSISTANT LECTURER (preferably with a good honours degree with suitable research and teaching experience, together with a good knowledge of both plant and animal biochemistry, with specialist qualifications in either) TO TEACH AGRICULTURAL BIOCHEMISTRY at the University of Malaya, Kuala Lumpur—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Kuala Lumpur and London, September 30).

LECTURER IN ANATOMY at the University of Western Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, September 30).

LECTURER or ASSISTANT LECTURER (preferably with a special knowledge and research experience in cytology or genetics) IN BOTANY at the University College of the West Indies—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (September 30).

LECTURER (preferably with qualifications in one or more of the following fields: climatology, geomorphology, biogeography, or the regional geography of North America) IN GEOGRAPHY at the University of Otago, Dunedin, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1, or The Registrar, University of Otago (New Zealand and London, September 30).

LECTURER (with particular interest in the Iron Age of Africa) IN ARCHAEOLOGY at the University College of Ghana—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (September 30).

LECTURER (with postgraduate qualifications and research or clinical experience, in addition to competence in general psychology, and preferably special qualifications in psychological measurement and the assessment of personality) IN PSYCHOLOGY at the University of Auckland, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (New Zealand and London, September 30).

SENIOR LECTURER IN SOIL SCIENCE in the Institute of Agriculture, University of Western Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, September 30).

SENIOR LECTURER IN PREHISTORY IN THE DEPARTMENT OF ANTHROPOLOGY, University of Auckland, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (New Zealand and London, September 30).

SENIOR LECTURER IN SOIL SCIENCE in the Institute of Agriculture, University of Western Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, September 30).

READER IN PHYSICS at St. Bartholomew's Hospital Medical College—The Academic Registrar, University of London, Senate House, London, W.C.1 (October 3).

LECTURER or SENIOR LECTURER (with a degree in pure science and/or in agriculture, preferably with postgraduate experience in genetics) IN GENETICS at Canterbury Agricultural College, University of New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (New Zealand and London, October 15).

AGRICULTURAL CHEMIST (with a good honours degree in agricultural chemistry or chemistry, and at least two years postgraduate research experience in agricultural chemistry) in Kenya, to take charge of research projects into soil and plant nutrition problems of coffee—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD.63/7/050/T.

ASSISTANT EXPERIMENTAL OFFICER (with a pass degree in physics or physical chemistry or H.N.C. or equivalent qualifications), to participate on both experimental work and the design of experimental apparatus—The Secretary, Low Temperature Research Station, Agricultural Research Council, Downing Street, Cambridge.

ASSISTANT LECTURER (Grade B) IN MATHEMATICS—The Clerk to the Governors, Chelsea College of Science and Technology, Manresa Road, London, S.W.3.

ASSISTANT LECTURER IN PHYSICS—The Registrar, The University, Nottingham.

ASSISTANT PROFESSOR or ASSOCIATE PROFESSOR (PHYSIOLOGIST, with an M.D. or Ph.D. degree, and capable of independent research) IN THE DEPARTMENT OF PHYSIOLOGY—Prof. M. Beznak, Department of Physiology, University of Ottawa, Ottawa, Canada.

CHAIR OF MECHANICAL ENGINEERING in the Faculty of Engineering of University College, Ibadan, Nigerian College of Arts, Science and Technology—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1.

CHEMIST (with a good honours degree in chemistry or equivalent professional qualification, and preferably specialization or experience in public analyst work) IN THE GOVERNMENT CHEMISTS DEPARTMENT, Government of Tanganyika, for general analytical work in the fields of toxicology, food and drugs, and water; and the supervision of assistants—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD.117/8/037.

DEPUTY DIRECTOR (with an honours degree in natural science, together with considerable postgraduate research experience, preferably not less than 10 years) OF AGRICULTURAL RESEARCH, Moor Plantation, Ibadan, Nigeria, to assist the Director of Agricultural Research in administrative duties—The Appointments Secretary, Federal Public Service Commission, Nigeria House, 9 Northumberland Avenue, London, W.C.2, quoting B.14/1.

HISTOLOGICAL SENIOR TECHNICIAN or TECHNICIAN IN THE DERMATOLOGICAL DEPARTMENT, mainly for research—The Secretary, University College Hospital Medical School, University Street, London, W.C.1.

LECTURER or JUNIOR LECTURER IN THE DEPARTMENT OF ZOOLOGY AND COMPARATIVE ANATOMY—The Secretary, The Medical College of St. Bartholomew's Hospital, West Smithfield, London, E.C.1.

LECTURER (preferably with a knowledge of heat transfer and its application to the design and operation of furnaces, etc., or practical experience of fuel using plant generally) IN FUEL TECHNOLOGY IN THE DEPARTMENT OF FUEL SCIENCE of the Houldsworth School of Applied Science—The Registrar, The University, Leeds 2.

PEST CONTROL OFFICER (preferably with a degree in general science and considerable practical experience in the control and elimination of insect pests and diseases of groundnuts) in Gambia, to eliminate or control insect pests and diseases affecting groundnuts and to enforce the Pest Control Legislation—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD.63/12/09/T.

PHYSICIST (Basic grade), for work which will include problems of dosimetry of a new type linear accelerator as well as the existing cobalt unit and conventional X-ray apparatus—The Superintendent, Guy's Hospital, London, S.E.1.

POSTGRADUATE STUDENTS IN (1) MOLECULAR QUANTUM MECHANICS, and (2) ORGANIC NATURAL PRODUCTS, IN THE DEPARTMENT OF CHEMISTRY, for work leading to M.Sc. or Ph.D. degrees—Head, Chemistry Department, University of Saskatchewan, Saskatoon, Saskatchewan, Canada.

RESEARCH ASSISTANT or TECHNICIAN (preferably with some experience of photography and/or workshop practice) IN THE PHYSICS DEPARTMENT, to help with experimental work on the strength of glass—The Professor of Physics, University College of North Staffordshire, Keele, Staffs.

REXCO RESEARCH AND DEVELOPMENT COMPANY RESEARCH STUDENTS (with, or anticipating to have, a good honours degree in chemistry, Grad.R.I.C., or a Dip.Tech. in pure or applied chemistry) IN THE DEPARTMENT OF PURE AND APPLIED CHEMISTRY, for the study of products from the low temperature carbonization of coal—Head of the Department of Applied Chemistry, Northampton College of Advanced Technology, St. John Street, London, E.C.1.

SCIENTIFIC OFFICER (with an honours degree in physics or physical chemistry) IN THE BIOPHYSICS SECTION, to undertake investigation of virus and antibody systems by such methods as electron-microscopy, analytical ultracentrifugation and optical analysis generally—The Secretary, Research Institute (Animal Virus Diseases), Pirbright, Surrey.

SCIENTIFIC OFFICER WITH THE DAIRY MARKETING BOARD of Southern Rhodesia, to set up and operate a central laboratory in Salisbury for the qualitative control of the Board's products, assume responsibility for laboratory control at the Board's factories, and to investigate the development of new milk products—The Secretary, Dairy Marketing Board of Southern Rhodesia, P.O. Box 587, Salisbury, Southern Rhodesia.

STUDENT TECHNICIAN (well-educated girl approximately 18 years) to assist in clinical research investigations on chests in the Surgical Unit—The Secretary, University College Hospital Medical School, University Street, London, W.C.1.

STUDENT (with good honours in a first degree in physics) IN THE DEPARTMENT OF PHYSICS, for research on the thermionic and related aspects of the direct conversion of thermal to electrical energy—The Professor of Physics, The University, Southampton.

UNDERSTANDING AND POWER

THE two aspects of science which Sir George Thomson discusses in his presidential address to the British Association for the Advancement of Science (see p. 837 of this issue) are its contribution to man's control over Nature and its contribution to our understanding of the nature of things. At the outset, Sir George firmly repudiates the idea that the contribution which science makes to our mastery of the world in which we live is the sole or even a sufficient justification for science. Without, however, examining science as one of the great human values, along with art and religion and philosophy, he defends so firmly and lucidly the value of science as a means of understanding the world in which we live that his address naturally recalls Sir Edward Appleton's address to the Association at Liverpool in 1953 on science for its own sake. Whereas, however, Sir Edward emphasized the intrinsic value of science, it is rather with the interrelations of science and technology that Sir George Thomson is concerned, and the way in which technological advance arises out of the contribution to our understanding of the physical world that science makes possible.

Science, Sir George points out, makes an approach to understanding which is the very opposite of that of religion and philosophy. It begins by studying details, often apparently trivial details, and from this study of details come concepts. Many of these do not survive, but the successful concepts, or the best of them, ~~are~~ no longer concerned with details. They penetrate deep in the heart of things and unify our thoughts over a vast area of facts, enabling men's minds to grasp certain aspects of the enormous complexity of the world. They represent an extension of the human intelligence, and often are not easy to comprehend, so that their subtleties oblige the popularizer to take care lest in simplifying he makes statements which are simply untrue.

Furthermore, Sir George maintains that concepts are discoveries as well as—indeed, more than—inventions, that they are more than an exercise or product of the human mind and represent reality. Here, where he points out that, as an exercise of the human mind, they equal the brilliance of any system of thought, philosophical or even mathematical, and when he sets science in its function of enlarging the bounds of human knowledge alongside the expression of human greatness in art and morals, he seems to come close to the line of Sir Edward Appleton's thought. It is the chance of understanding things of fundamental and permanent importance that makes the pursuit of science fascinating and worth while. This and, it might be added, the intellectual and moral discipline which it imposes on those who follow it, give science its place as one of the great human values.

Sir George Thomson, however, is more concerned in this address with the interactions of this aspect of science, as a way of finding out and understanding the world in which we live, on other aspects of life than with its value to the individual as an intellectual discipline or pursuit. In our times, technological advance, in the medical as well as in the engineering field, largely and even mainly arises out of clear understanding of the principles involved; though he reminds us that this has not always been true and that in earlier centuries advances in technology were largely empirical. To-day, discoveries are increasingly made in research laboratories and fewer by workmen on the bench, and industry in general recognizes this dependence of technology on pure science. Apart from a few industries where too little is spent on research or research is badly organized, Sir George believes the need is realized and reasonably well met.

Science itself, however, receives a great return for what it contributes to technology, and this in two ways, materially and in the realm of ideas. Indeed, though Sir George did not specifically say so, some science arises out of technology. Nevertheless, he pointed out that a modern physics laboratory could not work without instruments developed for technology and obtainable chiefly because industry needs them in large numbers, and he doubted whether academic scientists are sufficiently grateful for this return by industry. Without the resources which technology and industry have placed at his disposal, the power of the scientist to enlarge the boundaries of knowledge would be very considerably restricted, and this factor alone does not make it too easy to decide on the allocation of limited resources or whether to enter on some entirely new field.

Quite as important, however, is the influence of technology in keeping science in touch with reality. As science advances, concepts tend to become more and more abstract, and further removed from anything that can literally be touched or handled; and Sir George suggests that there is a danger that we may come to suppose that some elaborate piece of mathematics represents reality when it is only a creation of the mind, inspired indeed by physical reality, but no more like it than is a modern picture. So long as those who formulate these theories are reasonably close to those who use them, not merely in laboratories but also in industry, Sir George thinks that we are safe, and to him the most amazing thing about science and the most surprising and exciting thing about our world is the astonishing connexion between highly abstruse theoretical ideas and the matter of fact. Sir George illustrates his point by referring to a household kettle heated by electricity supplied by nuclear power; the argument for some effort in space research on the grounds of the probable benefit to telephonic communications is no more unrealistic than proposals for nuclear power would have seemed less than a generation ago.

In referring to these interactions of science and technology, Sir George joins issue with those who regard technology as intellectually a poor relation of science. To him, science without technology is incomplete and inconclusive. Systems of philosophy come and go, and it is hard to suggest criteria for their truth. When, however, conclusions deduced from precise experiments by mathematical theory lead to detailed predictions from which working machines can be designed, machines which without the theory no one would have thought of in a million years, then indeed one knows that one lives in a universe which is rational and that one has found the key to one of its rooms.

From this Sir George goes on to refer to some of the ways in which scientific knowledge has influenced and is influencing thought and the intellectual climate of the world. He believes that the quantum theory, for example, which had forced physicists, some of them very unwillingly, to believe that fundamentally the laws of physics are not statements of what must happen, but of the relative chances of a variety of alternatives, made quite a difference to the way one regards the universe, and that its consequences are still not realized by the average educated man. Yet these new ideas which science has provided, and is providing, new ideas tied closely to experience of a special character, constitute an achievement of which man may well be proud. It is surely something for beings, so utterly insignificant compared with the smallest of the stars that are scattered with reckless abandonment in the heavens, to be able to understand some at least of the principles which control their existence.

Sir George disclaimed any understanding of the relation between scientific concepts and reality, and some philosophers may well find the earlier part of his address provocative. It was not, however, the philosophy of science that he was concerned to display or the relations between science and philosophy; rather he sought to help some of those not closely concerned with science to understand something of the achievements of science in human thought, and the dependence of technological advance, or the increasing control over man's physical environment which technological achievement permits, on the advances in the fuller and deeper understanding of the physical world which science continually brings to us. "The full fruition of scientific work depends upon three things: the desire to know, the initiative to find out, and the awareness to apply"; in saying this in his tercentenary address to the Royal Society, Sir Cyril Hinshelwood recognized that scientific achievement is the result of the efforts of a small minority. Although Sir George Thomson did not attempt quite so large a canvas, his address is no less calculated to win the interest and assist the understanding of a wider audience in the work of men of science. What that small minority can achieve, either in the understanding or in the control of Nature, depends to some extent on the intellectual climate of its time, and the understanding and support it receives from the majority. The pursuit of knowledge should, as Sir Cyril implied, no longer remain the concern of the few; but, if the chronicler is to give more regular attention to the adventure and achievements of science, if the historian is to be induced to examine or record the interaction of scientific ideas with those of philosophy, politics or religion, much will depend on the determination and pertinacity, as well as the lucidity, with which men of science themselves seek to interpret the adventure of science in human understanding, no less than in extending our control of Nature to humanity in general. As Sir Cyril observed, the propagation of an idea demands the right conjunction of unknown human factors; but even when these are propitious, nothing will initiate the change save the operation of a minority, perhaps even beginning with an individual. But the majority and the individual are in mutual dependence for, except under rare conditions, the individual in isolation is impotent. To create mutual understanding and, it might be added, confidence, between the creative minority and the majority on which the minority is dependent for resources, is an essential task in science as in art; and Sir George Thomson's penetrating exposition of the relations between the two aspects of science—extension of human understanding of the world in which we live, and the enlargement of man's power of controlling the material forces and resources of that world—is best appreciated as an effective essay to that end.

IONOSPHERIC PROPAGATION OF ELECTROMAGNETIC WAVES

The Magneto-Ionic Theory and Its Applications to the Ionosphere

A Monograph. By J. A. Ratcliffe. Pp. x+206. (Cambridge: At the University Press, 1959.) 40s. net.

THE propagation of electromagnetic waves through a gaseous ionized medium in the presence of a magnetic field is a very complicated problem in its full complexity. It is fortunate that, for applications to the ionosphere, certain simplifications may be made. Thus it is rarely necessary to take explicit account of the wave character of the propagation—attention can be concentrated on the determination of the indices of refraction and of absorption. Even so, there is a great number of factors to take into account and it is extremely difficult to see how each is effective, as well as to be aware of all the different possibilities which can arise. It is therefore fortunate that one of the most skilful exponents of the subject has written this monograph with an eye always towards applications to the ionosphere.

The book is planned on a very systematic basis with the careful attention to detail which is so necessary in presenting this subject. On the other hand, the treatment is by no means purely mathematical. Indeed, special attention is devoted to discussing the physical significance of the various formulæ and approximations which are introduced.

The introductory chapter includes a historical account of the development of the subject, which is of much interest and includes a summary of the nomenclature which is used consistently throughout the book. Part I is concerned with the derivation of the equations. Both macroscopic and microscopic approaches to the problem are described in successive chapters, special attention being directed in two following chapters to the discussion of absorption.

The equations obtained are complex, and Part 2 is devoted to a detailed discussion of this interpretation. A gradual approach to the most-general case is skilfully employed so that the maximum insight into the significance of the different contributory effects can be obtained. The successive chapters deal with the graphical representation when there are no collisions, the polarization of the waves, the quasi-longitudinal and quasi-transverse approximations, the effect of collisions on the indices, some representative curves of the indices, and the group velocity.

A similar gradual approach is used in Part 3, which deals with applications to the Earth's ionosphere. Thus Chapter 12 deals with a model ionosphere with no magnetic field, to be followed by one in which the effect of a magnetic field is included. The concluding chapter of this part gives an interesting account of the nature of the motion of electrons in the ionosphere in the presence of the Earth's magnetic field.

The last part deals with some miscellaneous subjects. Chapter 15 discusses the question of whether the Lorentz term should be included in the expression for the complex refractive index and Chapter 16 examines the effect of the presence of heavy ions. In Chapter 17 the restriction otherwise maintained of dealing with a homogeneous medium is lifted and many new effects which can then arise are discussed. The final chapter compares and contrasts the propagation through the magneto-ionic medium with that through an anisotropic medium such as a crystal. An extensive bibliography is provided.

This monograph is a masterly work written by a great expert not only in the subject but also of exposition. It cannot fail to be of great value to all who are interested in the ionosphere and related subjects. Its appearance at a time when new possibilities of research in radio propagation have been opened up through the use of rocket and satellites is most opportune.

PROPOSALS FOR SPACE FLIGHT

The Exploration of the Solar System

By Felix Godwin. Pp. 200+10 plates. (London: Chapman and Hall, Ltd., 1960.) 35*s*. net.

THIS book represents an attempt to outline the probable development of astronautics between now and the year 2100, with many detailed accounts of possible expeditions, based on the assumption that only currently foreseeable techniques are used. The first topic discussed is the near-Earth assembly orbit, which will serve as the base for space-ships; then the problems of instrumented and manned expeditions to the Moon are reviewed. Next there is a lengthy and detailed plan for the exploration of Venus, followed by a similar one for Mars. The main text ends with a long chapter on further possibilities, such as visits to the outer planets, plasma rockets and interstellar flight. Finally, there are several appendixes, on topics such as rocket propellants, personnel, space warfare and costs, a glossary and a full index.

Although inevitably there is much that is speculative in the book, the factual detail is piled up with such convincing realism that the reader is often persuaded to suspend disbelief. Many authors of books on space flight give the unfortunate impression that to travel enthusiastically is better than to arrive, but Mr. Godwin's expeditions have a clear aim—to make thorough scientific investigations of the planets—and travelling is merely the means to an end. The author writes in the present tense, as if all the complex operations he describes were matters of routine, and for him there is no gap between the possible and the practical. This might be thought a fault, and attributed to his youth—for he wrote the book between the ages of sixteen and eighteen. But in a book about the future, there would seem to be no harm in recognizing the truth that the technological impossibilities of one generation are the commonplaces of the next. It must be emphasized, too, that the author has voluntarily limited himself to foreseeable techniques: with the development of unforeseen ones, his plans may come to seem timid rather than over-ambitious.

Mr. Godwin evidently has a wide knowledge of most aspects of space technology and physics, but there are plenty of flaws to be found among the crowded detail of the book. His schemes, though ingenious and well thought out, are sometimes out of touch with present practice: for example, solar batteries are not mentioned except in a brief paragraph on p. 124, though power supplies are often discussed earlier. He relies too much on space-flight books of the early 1950's, some of which are now seriously out of date. His use of symbols is undisciplined; for example, the symbol *a* on pp. 24 and 25 is not only undefined but has two different meanings. Pp. 74–76, explaining in detail the optimum manoeuvre for a tanker intercepting a returning space ship, seem to be erroneous: the tanker's weight could be reduced by a factor of about 3 if the transfer were made near perigee. One could go on finding fault in this way, but such flaws do not destroy the book's real merit of providing a logical and well-founded outline of the probable future exploration of the solar system. The reality will, no doubt, be different, but only because of advances not yet predictable.

D. G. King-Hele

GENERAL AND LINEAR CIRCUIT THEORY

General Circuit Theory

By Prof. Gordon Newstead. (Methuen's Monographs on Physical Subjects.) Pp. vii+144. (London: Methuen and Co., Ltd.; New York: John Wiley and Sons, Inc., 1959.). 15*s*. net.

THIS book is a welcome addition to Methuen's series of monographs on physical subjects. Prof. Newstead has undertaken the ambitious project of outlining a general circuit theory in 140 small pages and has succeeded to a remarkable extent.

It might have been better to have expanded the book into two volumes; one for steady-state theory and the other for transient theory. The author would then have been able to develop his generalizations at greater length and his arguments would have been easier to follow. In its present form the book is scarcely suitable for those seeking an introduction to the subject and is more suitable for experts.

The starting point of the book is the linear differential equation for two terminal networks :

$$i = \Sigma_r a_r D^r e$$

where r has zero, positive and negative integral values and $D \equiv d/dt$. The bulk of the book is confined to the treatment of the linear circuit theory following from this equation and Kirchhoff's laws. The author allows himself only ten pages in the last chapter to deal with non-linear theory, but gives here a most attractive presentation of the methods used for tackling non-linear problems. The importance of this ever-growing class of problems is scarcely underlined by such a meagre allocation of space, and it is to be hoped that another monograph from the same author will soon appear providing a generalized treatment of non-linear problems.

In the first three chapters of the present book the author develops from the above basic equation the concept of circuit components and then proceeds with the development of general network theorems and the treatment of the 4-terminal network in the steady state. There follows a chapter on "The Fourier Integral" and the treatment of network transients.

The book is mainly mathematical in character.

A. H. M. ARNOLD

CHEMICAL PHYSICS COMES OF AGE

Advances in Chemical Physics

Vol. 1. Edited by Prof. I. Prigogine. Pp. xi+414. 87*s*. Vol. 2. Edited by I. Prigogine. Pp. ix+412. 87*s*. (New York: Interscience Publishers, Inc.; London: Interscience Publishers, Ltd., 1959.)

DURING the past fifty years we have seen the development of several new branches of chemistry—physical chemistry, radiation chemistry, quantum chemistry. All of them were associated with the incursion of new physical techniques or mathematical theories, and their subsequent exploitation within the total framework of chemistry. Chemical physics is a very vigorous child, with parentage in physics and mathematics as well as in conventional chemistry. At the research-level it is well catered for by the American *Journal of Chemical Physics*, the British *Molecular Physics* and other journals elsewhere. But the time has come when no one can follow all its development. Review summaries are required. The 'baby' has come of age.

These two volumes follow the general style and format of other sets of "Advances in . . .". Each consists of a series of ten to twelve articles, written by someone working in a particular section of the field, and setting out the major developments in the preceding years. The articles are very varied in topic—from isotope effects in chemical kinetics, through the electronic description of atoms and molecules to nuclear quadrupole resonance and clathrate solutions. They also vary in length—from 15 pages on transport theory in binary liquid solutions to 116 devoted to what is probably the most complete account hitherto presented of the calculation of correlation energy in many-electron problems. Some of the essays are easy to read, such as Bright Wilson's account of the barriers to internal rotation; others, such as Kihara's on the non-additivity of intermolecular forces, are much more difficult.

Prof. Prigogine, who edits this series, has started well. His choice of authors is excellent, and the range of topics almost entirely suitable. One is tempted to say that there is now developing a rather clearer acceptance of what 'chemical physics' really is. It has been defined by no one, but has grown with the subject. It is not chemistry, because continually physical concepts and techniques are used. Nor is it physics, because the language and thought-forms of chemistry belong to it. It is an outlook—a way of looking at things—with a certain degree of austerity in its discipline (as befits physics) and a satisfaction with understanding a phenomenon, even when you cannot completely calculate it (as befits chemistry). It makes unashamed use of mathematics, yet the mathematics is never the *raison d'être*. There are as yet practically no university chairs in it; but its arrival (so well documented in these annual volumes) has probably made as much difference to chemistry as any development since the atomic theory. Long may we continue to look for convenient summaries of its progress, similar to these present ones.

C. A. COULSON

MOLECULAR GEOMETRY

The Determination of Molecular Structure

By P. J. Wheatley. Pp. vii+263. (Oxford: Clarendon Press; London: Oxford University Press, 1959.) 35*s*. net.

A DISCONCERTING modern trend which this book serves to underline is the increasingly divergent scientific outlooks of the workers in different branches of chemistry. They tend even to attach different meanings to the words they use. For many decades past the classical organic chemist has used the expression 'molecular structure' to denote the arrangement of atoms in molecules and the manner in which they are linked. Mr. Wheatley uses the term in the more precise sense of configuration and molecular dimensions. From this point of view he is no doubt justified in his reference to the "uncertainty attached to many chemical arguments" and in saying that "nowadays an appeal is almost always made to the more reliable physico-chemical methods". But the traditional chemical methods of determining molecular constitution are by no means obsolete, and there is no immediate prospect that they will soon be superseded.

To the theoretical chemist it may well be true that "the object of any scientific experimentation is the elimination of further experimentation". This is another respect in which the author's attitude is very different from those who pursue other branches of the science.

Mr. Wheatley's book gives a brief and interesting survey of modern physical methods used in determining the sizes and shapes of molecules. There are a section on spectroscopic methods (excluding ultra violet absorption), a considerable section on diffraction methods (mainly X-ray diffraction of crystals but including also electron and neutron diffraction and a third section on miscellaneous methods, including dipole moments and nuclear magnetic resonance. The approach is theoretical rather than practical but care is taken to indicate the types of information that can be obtained by the application of the methods discussed. At the end of each chapter are useful references to more extensive publications on the subjects under discussion. J. W. Cook

GENETICS OF CONTINUOUS VARIATION

Introduction to Quantitative Genetics

By D. S. Falconer. Pp. ix+365. (Edinburgh and London: Oliver and Boyd, Ltd., 1960.) 35s. net.

THE genetical study of continuous variation has had a somewhat chequered career. To Darwin this was the variation that mattered above all, and it was the variation to which Galton and later Pearson devoted their unsuccessful efforts to work out the principles of heredity. To the early Mendelians, however, it was, one feels, a puzzle and even a nuisance, intractable by their techniques and a source of acid dispute. True, the basis for understanding its determination and properties was laid down during this period; but its experimental study was so much more tedious and its theory so much more mathematical that for several decades it just failed to hold its interest in the face of the more classical type of genetical study. Now the situation has changed again. The significance of continuous variation in wild populations and its key importance for plant and animal breeding are fully recognized, and the past fifteen years or so have seen a tremendous growth in its genetic study. Its problems and perhaps even more its analytical techniques may still set it apart as a somewhat specialized branch of genetics, but it is as essential to an appreciation of the science at one end as cell chemistry, deoxyribonucleic acid and gene structure are at the other.

Dr. Falconer has now given us a text-book of, as he terms it, "Quantitative Genetics", and we are indebted to him for it. It is a noteworthy book in several ways. To most biologists it will read more like a text-book of physics than like the type of biological literature with which they are familiar, so much is mathematics an integral part of the structure. Yet we should be grateful that the mathematics is never oppressively advanced or complex—a virtue which will be acknowledged the more readily by those who have attempted other texts in this field. Within its ambit it covers the ground admirably, and its length serves only to indicate the amount of ground to be covered. The behaviour of genes in populations, variation, heritability, selection, inbreeding and heterosis, particularly as they appear in animal experiments, are all dealt with lucidly as well as carefully: indeed in places, as where family selection is analysed and discussed, the treatment is of a notably high order. Occasionally a laxness of expression creeps in, as where it is said that the "partition of (phenotypic) variance into genotypic and environmental components formulates the problem of . . . the relative importance of genotype and environment in determining the phenotypic value"—surely one of the oldest *non-sequitur* in the history of genetics. At times, too, the argument is more than a little tendentious; but these periodical blemishes can weigh only lightly in the balance against the generally consistent quality of the book.

The risk of a book such as "Quantitative Genetics" lies elsewhere, in its very success in presenting the mathematically analytical approach. Mathematics has a charm of its own, in the clarity, generality and finality with which its conclusions emerge. These, however, can never be sounder than the evidence, postulates and concepts from which they are derived, and the charm becomes meretricious if it blinds us to the limitations of the situations, the complexities of the relations or the uncertainty of the premisses we are exploring. Dr. Falconer, for example, spends little time on linkage: he largely contents himself with reiterating the charge that mathematics has shown it cannot have much importance in relation to selection while ignoring the experimental evidence that it is in fact not so lightly to be dismissed. He discusses correlated response to selection wholly in terms of pleiotropy, which is easy to handle by correlation technique, but overlooks the cases where linkage supplies, to say the least, a much more satisfactory interpretation of the experimental results. He argues for a simple relation between heterozygosity and fitness but barely mentions the self-fertilizing plants which show that this relation must itself be the product of natural selection in the past. He states that the genes governing number of bristles in *Drosophila* show no dominance, and bolsters his contention that this character is selectively neutral by postulating hypothetical pleiotropic effects of these genes while supporting his view by reference to evidence which is at least as readily interpretable in the opposite way. In justice to Dr. Falconer it must be said that most of these opinions are to be found in the final chapter, which he himself describes as setting out his own views on controversial topics. This is a praiseworthy warning, for indeed whatever disagreement we may feel with these final sections should never be allowed to blind us to the great value of the other nine-tenths of the book, or to the debt we owe Dr. Falconer for so ably presenting the subject, especially as it appears to the animal geneticist, for the benefit of all our students. Kenneth Mather

THE YELLOW FEVER MOSQUITO

Aëdes aegypti (L)

The Yellow Fever Mosquito—Its Life History, Bionomics and Structure. By Sir S. Rickard Christophers. Pp. xii+739. (Cambridge: At the University Press, 1960.) 75s. net.

THE yellow fever mosquito is a most appropriate subject for a large treatise. Of all mosquitoes it is that most easily maintained in culture in the laboratory. Its most characteristic breeding site is the small tree-hole containing an ounce or two of water, very liable to dry up. The eggs stranded under these conditions can withstand desiccation for many months and hatch in a few minutes when immersed in water; abundantly fed, they reach the adult state in a few days. It is therefore a most valuable experimental animal upon which much of our knowledge of the physiology of mosquitoes in general has been based. It has been extensively used as a test object for insecticides and repellents.

Few insects have suffered more at the hands of taxonomists than this mosquito. It is now generally known as *Aëdes aegypti* Linnæus 1762. It may or may not be the insect briefly described by Linnæus under that name—but after so many tiresome changes it is to be hoped that the name will stick. *Aedes aegypti* occurs throughout the entire tropical belt around the globe, and extends for a variable distance into the subtropics. Throughout most of its range it is a domestic insect, rarely breeding more than a few yards from human habitations. It was incriminated by Reed and his colleagues (1900) as the carrier of urban yellow fever; it also carries the virus of dengue fever. It is therefore an insect of great importance to mankind.

The effective control of *Aedes aegypti* in Havana and Panama, with the elimination of yellow fever, gave promise that the disease could be eradicated from the New World. But the attempt at eradication by the Rockefeller Foundation brought to light the existence of a sylvan form of the disease maintained by other mosquitoes in monkeys and other mammals in the jungle and spreading only occasionally to man, and so to his domestic mosquito. The same epidemiological pattern has been found in tropical Africa; and rural forms (genetic strains) of *Aedes aegypti* have been recognized which can also be involved in the transmission of the rural disease.

As the years have passed the subject of yellow fever and its main carrier has become ever more complicated. It will be a great boon to have this erudite and practical treatise on hand, dealing as it does with all aspects of the morphology, physiology, biology and control of *Aedes aegypti* (much of the morphology being original), written by an author who has been an authority on mosquitoes since he was a member of the Malaria Commission of 1899–1902, combining a sense of history with a good account of the most modern work, and beautifully produced. It will not be difficult to find small omissions of recent work, but it is to be doubted whether any other author could have written such a well-proportioned survey of this many-sided subject. It was a wise and generous decision of the Rockefeller Foundation to make possible the publication of this book.

V. B. WIGGLESWORTH

EMBRYOS OF BIRDS

The Avian Embryo

Structural and Functional Development. By Prof. Alexis L. Romanoff. Pp. xvi+1305. (New York and London: The Macmillan Company, 1960.) 210s.

SOME ten years ago, Prof. Romanoff, who holds the chair of chemical embryology at Cornell University, published in collaboration with his wife a massive compendium on the avian egg. He has now proceeded to a detailed consideration of the embryo within the egg. Embryos of the domestic fowl have been perhaps more widely and thoroughly studied than those of any other vertebrate. Romanoff's monograph is certainly the most complete that yet exists in this field. Moreover it covers the embryo not only of the fowl but also those of all other birds in so far as they have been studied. It is therefore an invaluable work of reference, and there can be no embryologist who does not feel a debt of gratitude to the author for the enormous labour which must have gone to its compilation.

Romanoff states that in the preparation of this book it was necessary to make a critical study of more than 7,000 original publications, about two-thirds of which were written in languages other than English. Of these only some 2,700 are cited in the text; but that is already a much more extensive bibliography than is available elsewhere. Moreover, the list of references is at the same time an author index, giving reference to the page of the text in which the work referred to is discussed. One perhaps slightly odd feature of the bibliography is that no mention is made of the other recent monographic works on the chick, such as Hamilton and Hamburger's revision of Lillie's book, the Willier-Weiss-Hamburger "Analysis of Development" or my own "Epigenetics of Birds". On the other hand, the references to original publications give evidence of truly catholic reading, and will be found particularly valuable by English-speaking readers to whom the contributions published in other languages may not be so easily available.

The first three chapters cover the reproductive cells (70 pages), fertilization and fertility (40 pages), and early morphogenesis (about 95 pages). In the last-named chapter it is particularly gratifying to see full accounts of the work of the real pioneers of the modern period of our knowledge of gastrulation and associated processes in the chick, such as Gräper, Wetzel and Pasteels, which in some of the recent American monographs has tended to be somewhat neglected in favour of more recent American work. The experimental studies on these stages has also been very well reviewed. It is perhaps noteworthy that Romanoff does not use, and so far as I can make out, does not even mention the conventional numbered stages into which the development of the chick embryo has been divided, for example by Hamburger and Hamilton. Personally, I find the use of such stage numbers an unnecessary impediment to ease of understanding. If one refers to an embryo as in the long streak stage, the head process stage, or the three somites stage, everyone knows immediately what is meant, whereas reference to stage 13 conveys nothing except to the expert and saves only a minimal amount of breath or printer's ink. However, many embryologists appear at the present time to favour the use of numbered stages, and it would perhaps have been valuable if Romanoff had at least listed them.

After these three introductory chapters there follow more than 900 pages devoted to the description of the development of the various organ systems, including the extra-embryonic membranes. It is clearly impossible to review these in detail; it can only be said that a vast body of information is here assembled together and that the choice and arrangement of materials show evidence of a good critical insight. A subject index of more than 60 pages in addition to the bibliography author-index make it possible for the reader to find his way about. The book also contains some 440 illustrations which comprise in all more than 2,250 separate drawings. In spite of the size of the book these have had to be reproduced on a comparatively small scale, but they have been re-drawn in a simple style so that nearly all of them remain quite clear even after reduction.

Both in the wealth of detail it includes and in the balance and fairness of its account, Romanoff's book is far in advance of any previous monograph on the bird embryo. It will certainly remain the standard work of reference in this field for many years to come.

C. H. WADDINGTON

ASPECTS OF PLANT NUTRITION

Nutrition of the Legumes

Proceedings of the University of Nottingham Fifth Easter School in Agricultural Science, 1958. Edited by Prof. E. G. Hallsworth. Pp. x+360. (London: Butterworths Scientific Publications; New York: Academic Press, Inc., 1958.) 55s.

Utilization of Nitrogen and its Compounds by Plants

Symposia of the Society for Experimental Biology, No. 13. Edited by H. K. Porter. Pp. vii+385. (Cambridge: At the University Press, 1959. Published for the Company of Biologists on behalf of the Society for Experimental Biology.) 50s. net.

THIS is an age of conferences, and both the Society for Experimental Biology and the Agricultural Department of the University of Nottingham can claim a high degree of success for those they organize in their respective fields of interest. In 1958 the topics of the Symposium of the Society for Experimental Biology and of the University of Nottingham Fifth Easter School in Agricultural Science overlapped considerably, for in a discussion on the nutrition of legumes, the subject of the latter, the uptake and utilization of nitrogen, the subject of the former, must obviously demand a leading, though by no means exclusive, part.

In the Nottingham Easter School the various aspects of legume nutrition were well covered by the twenty-four papers provided by the various contributors. These papers were classified in five groups: the plant component, the rhizobial component, the symbiotic system, biochemical aspects and field aspects. The papers in the first group, apart from one on the classification of the Leguminosae by Prof. Tutin, were concerned with mineral nutrition, particular attention being given to micronutrients and aluminium. Among the second group were contributions on the classification of *Rhizobia*, the physiology of nodule formation, the survival of the root nodule bacteria outside the host plant and a general consideration of the symbiotic fixation of nitrogen in the Leguminosae. The third group of papers was largely concerned with factors affecting the uptake of nitrogen by legumes and factors affecting nodulation, but included in this group was a paper by Dr. G. Bond on symbiotic fixation of nitrogen by eight genera of angiosperms outside the Leguminosae. The biochemical aspects considered in the fourth group were nitrogen fixation, the transport of amino-acids, and the effect of iron deficiency on amino-acid metabolism in the yellow lupin. The papers concerned with field aspects dealt with a rather miscellaneous assortment of topics ranging from the tolerance of lucerne to excess manganese and copper deficiency in the field to the growth of a clover sward.

In the Symposium of the Society for Experimental Biology the emphasis was mainly biochemical, as was to be expected when the theme was the utilization of nitrogen. The course of nitrate reduction and the enzymes concerned in it, various aspects of the metabolism of amino-acids, including their assimilation and utilization, the biosynthesis of amide and peptide bonds, the formation of alkaloids, and the relation of nucleic acids to plant growth and development, were among the subjects of the twenty papers contributed to the Symposium.

The papers presented at both these conferences varied considerably in respect to the amount of original unpublished information contained in them. It would perhaps be best to regard them as essays giving an up-to-date account of the respective subjects with which they dealt, written by experts actively working in their various fields. As such they provide a wealth of information on the nutrition of the Leguminosae and the utilization of nitrogen by plants in general.

The esteem in which these conferences are held and the value placed on them by the participants is indicated by the number of overseas visitors taking part. In the Nottingham School 40 per cent, and in the Society for Experimental Biology Symposium 50 per cent of the papers were given by workers abroad who came from Australia and New Zealand, Canada and the United States, Belgium, Holland, Denmark, Finland, Germany and the U.S.S.R. WALTER STILES

PARASITIC HELMINTHS

Medical Helminthology

By Dr. J. M. Watson. Pp. xi+487. (London: Baillière, Tindall and Cox, Ltd., 1960.) 84s.

TO summarize, in a convenient form, all the work that has been done in the past half-century on the human diseases caused by helminths is not an easy task; and when an author includes, as Watson does, references to diseases caused in other animals by these parasitic worms, the task is greater still. Watson has, however, had long experience of his subject. He was senior helminthologist to the Wellcome Laboratories in London, served as a member of the World Health Organization's Expert Committee on Parasitic Diseases and has been professor of zoology and of parasitology and bacteriology in the University of Baghdad. The book he now gives us is based on lectures he gave at the American University of Beirut, and the manuscript of it has been checked by English, Canadian and American experts whose names are household words in the field of parasitology.

Part I of the book is a general introduction to the subject, which reviews the comparatively brief history of helminthology and discusses the zoological position of parasitic helminths, their relations with their hosts and the geographical distribution of the important species which infect man. In the bulk of the book (Part 2) the author gives an account of the helminths themselves, arranging these, not, as most text-books on this subject do, according to their zoological position, but according to the tissues which they attack. This is, the author thinks, clinically more convenient and no doubt many will agree. Others will prefer the zoological plan, which at least has the merit of bringing together the types of lesions caused by nematodes, cestodes and trematodes, respectively. The third part of the book discusses the diagnosis, treatment and prevention of helminth infections, and appendixes provide a bibliography, all too short, some may think, of key references to the vast literature, a valuable chapter on the rules of zoological nomenclature and another, which research workers will find useful, on the helminth infections of common laboratory animals. In his final chapter the author gives, among other facts, notes on the rapid recent advances in our knowledge of vectors and anthelmintics.

It is not possible, in a brief review, to discuss detail in a book as extensive as this one and, in any event, the criticism of detail is best left to the teacher or the research worker who uses the book and advises students about it. But a word must be said in praise of the 62 figures, most of which are made up of several individual line drawings, among which are silhouettes of parasitic helminths which give their natural size, a useful feature which appears in other books, but not to the extent to which it is here employed. The production of the book must also be praised; it is well printed, in clear type, in parallel columns on a large page and, unlike some very heavy text-books on this subject, it is delightfully light.
G. LAPAGE

PLANNING FOR THE CHANGING WORLD POPULATION

Our Developing World

By Prof. L. Dudley Stamp. Pp. 195. (London: Faber and Faber, Ltd., 1960.) 21s. net.

PROF. DUDLEY STAMP gave the Patten Foundation Lectures at the University of Indiana in 1950. These lectures were expanded and published in 1952 by the Indiana University Press and the American Geographical Society under the title "Land for Tomorrow", and were revised for the English edition "Our Undeveloped World", published in 1953.

Rapidly changing world populations, land-use values and food supply, urbanization, and new developments in farming, in mechanization of agriculture and in plant and animal genetics during the past seven or eight years have made further revision necessary, and "Our Developing World" now appears as a new book emphasizing the same fundamental point of view of the author on the ever-increasing pressure of population on land resources and incorporating, where appropriate, much material from the two earlier books, but also bringing new thought to the problems of under-developed lands.

At the present rate of increase, world population will be doubled in less than forty years. This problem and its related one of planning land use are considered on the world-level, the national level with extremes of wealth in some countries and poverty in others, the regional level and local level. Farming is rapidly becoming a specialized industry. The proportion of population engaged in farming is decreasing almost all over the world, and while the movement is generally away from subsistence farming to commercial agriculture it must not be assumed that increasing industrialization and decreasing agriculture are necessarily the panacea for all ills associated with under-development.

Increasing urbanization is a pressing problem, and growth of cities cannot easily be limited. Efforts should be directed towards improving the urban environment as part of a correct land-use programme. The need for mapping the present distribution of population is as important as that for mapping the use of land, and a Commission has been set up by the International Geographical Union for the study of this problem. The geographical distribution of pests and diseases in man, animals and crops is another contributory study to population and land-use problems.

Prof. Dudley Stamp's conclusions are that world starvation is not just around the corner, that the population of the Earth could be increased to many times its present number without starvation provided man-made barriers are broken down and food is produced efficiently by a comparatively small number of specialist farmers.
M. K. MILNE

CONTINUITY IN A SMALL PACIFIC ISLAND

Social Change in Tikopia

Re-Study of a Polynesian Community after a Generation. By Raymond Firth. Pp. 360+8 plates. (London: George Allen and Unwin, Ltd., 1959.) 45s. net.

TIKOPIA is an isolated speck of land seven miles in circumference with a population of fewer than 2,000 souls; it is one of the smallest of the small islands on the periphery of the British Solomon Islands Protectorate, of which entity it has been politically since 1898 a remote outlying fragment. The nearest land is another islet, Anuta, 70 miles to the north-east; the nearest administrative officer of the Protectorate resides at Vanikoro in the Santa Cruz Group, 130 miles away; it is 500 miles distant from the Solomon Islands proper.

This dot in the Pacific Ocean is inhabited by a community of Polynesians left behind during the great migrations that led the main branches of the race on to Samoa and Tonga, the Ellice and Cook Islands and Tahiti, to Hawaii in the north, New Zealand in the south and Easter Island in the far east of the Pacific. Cut off since those migrations from the centres of Polynesian life, the people of Tikopia and of the other islets in the Solomon Islands' "Polynesian Fringe" have continued to live in isolation as they had always lived; even in the first half of this century they were seldom visited more than about once a year by a Mission ship or a government officer. Before the Second World War, practically no Tikopians ever left their island (except perhaps for a temporary sojourn in Anuta) to return with new ideas from the outside world of other Pacific islands, for a paternal if distant Government wisely forbade recruiting-vessels to take them away to work elsewhere.

Tikopia was therefore the perfect subject for a detailed anthropological study; and in 1929 Prof. Raymond Firth concluded a long and solitary residence with this small, homogeneous and hitherto unchanged community; the principal findings of his study were published as a substantial volume in 1936 under the title "We, the Tikopia". After an interval of twenty-three years he decided to re-investigate the Tikopians (on this occasion in the company of a colleague) partly "to throw some further light on the analysis of the dynamics of small-scale integral social systems", but more particularly to ascertain what had happened to these hitherto sheltered islanders in a period that had seen, owing largely to a world war, such drastic changes in other parts of the Pacific.

What did he find? The first and most obvious impression was the sad destruction wrought by a hurricane shortly before his return, with its resultant grave reduction of foodstuffs and threat of famine. He then found, as he pursued his investigations, that the War had left Tikopia alone since, luckily for its people, it was off the line of the Solomon Islands campaign. The Tikopians, he says, "were spared the traumatic experience of most other islands; neither the Japanese nor the Americans established a base there".

But he also found that a few of the islanders had, after the War, gone to work in the Solomon Islands proper; that the people's geographical notions, previously more or less confined to Anuta and perhaps Vanikoro, had consequently received a modest expansion, that Christianity as taught by the Anglican Melanesian Mission had increased its majority over paganism, that money was beginning to co-exist with barter.

When Prof. Firth first resided in Tikopia, the men of the island presented a striking appearance of a bizarre and unique kind; tall, slim and well-built, they grew their hair as long as possible and bleached it with applications of lime to a golden shade, so that at a distance they seemed to be maned like lions. This was still the case when I myself visited the island more than a decade later, just before war came to the Pacific. On his return, Firth found that most of the younger men were wearing their hair short, and that some of the canoes that came out to meet him were paddled by exclusively female crews, "a striking cultural novelty".

Tikopia is too distant from any Government centre and too small for direct administration, even if this were thought to be suitable. Thus, the traditional local forms of autonomy have had the chance to survive; and Prof. Firth thinks that, even with increasing contact with the Government, the power of the chiefs is likely to grow so long as the Government accepts their authority. "With the clearer emergence of the Tikopian Chief as a secular power, recognition of him as such by the Government is likely to consolidate his general status".

Some artists—Tintoretto, for example—work on a vast canvas; others choose the technique of the miniature. Prof. Firth, in his two major books on the Tikopians, belongs to the latter class. He has devoted an appreciable period of his life to the study of a tiny community—1,200 souls during his first stay, 1,700 on his return—and he has dealt with it in the utmost detail. He has done well to do so, for Tikopia is not only, as he points out, "a highly structural society" but it is also a homogeneous one, saved by its geographical isolation from the drastic and sometimes disastrous changes that the Second World War has wrought in other primitive communities. He has, by this full account of his return to the scene of his former studies, conferred a benefit on all students of the Pacific. H. C. Luke

FACT AND OPINION

The Anatomy of Judgment

An Investigation into the Processes of Perception and Reasoning. By Dr. M. L. Johnson Abercrombie. Pp. 156+7 plates. (London: Hutchinson and Co. (Publishers), Ltd., 1960.) 25s. net.

The author of this short book is a zoologist who has been much concerned with the selection and training of medical students. As a university teacher, she had become increasingly sceptical about the effects of an ordinary scientific education upon the capacity to think, and was therefore led to embark upon a most courageous experiment in education. This, essentially, was a free discussion class in which a dozen or so students were tactfully prevailed upon to scrutinize their own processes of observation and inference. For example, a discussion built around the incidence of 'observer error' in the interpretation of radiographs served to bring out the role of hidden inferences in the reporting of 'facts'. Other discussions were concerned with the meanings of words (for example, the word 'normal' as used in biology or medicine), with the rationale of classification and the evaluation of evidence. These classes were certainly not meant to provide formal instruction in logic or scientific method. Rather was it hoped that the participants, by gaining insight into their own preconceptions, would gradually attain a more original and genuinely objective approach to scientific issues. Although it is difficult to be sure, there is reason to believe that the new method achieved a very fair measure of success.

Although mainly concerned with cognitive issues, Dr. Johnson Abercrombie clearly finds it essential to devote some consideration to factors of temperament. Indeed she has gone out of her way to learn something of the techniques of modern psychotherapy and traces a most interesting parallel between her discussion classes and group psychotherapy. In both settings, discussion of topics apparently impersonal may serve to uncover insecurities at a deeper level. It follows, therefore, that educational experiments of the kind Dr. Johnson Abercrombie describes are not to be undertaken lightly. None the less, if we are to make the best of scientific education, it seems essential that we should discover ways to liberate the student from the security of his accepted patterns of opinion and thought. Dr. Johnson Abercrombie's work is at least a first step in this direction and, after all, *c'est le premier pas qui coute*.

Dr. Johnson Abercrombie's experience has stimulated her to inquire seriously into the psychology of perception and judgment and to attempt to place her findings within a broader psychological context. Indeed, the first part of her book provides a useful review of modern work in this field, with particular reference to the parts played by attitudes and experience in governing perceptual activity. Although her account is quite well done, it cannot perhaps be said to add anything to the numerous accounts of the subject already available. The value of this book lies above all in the description given of a fascinating real-life experiment and in its very real implications for the theory and practice of education.

O. L. Zangwill

FRANCIS BACON WITHOUT HIS BACKGROUND

Francis Bacon

The First Statesman of Science. By J. G. Crowther. Pp. xv+362+7 plates. (London: The Cresset Press, 1960.) 35s. net.

This big book falls into two parts. The first, "For Mankind", is an attempt to estimate Bacon's scientific achievement. The second part, "For Himself", offers a biography of the statesman. The suggestion here, that Bacon was in politics for private ends, is unfortunate, and does not really represent Crowther's view. For he has written a full and sympathetic study of Bacon's public career, which can be read with pleasure and is, in my judgment, the more successful portion of the book.

Of the first part it is not possible to speak so favourably. The character and the greatness of Bacon's reform of knowledge can only be brought out by a strictly historical approach. Before he could clear the path for an active philosophy of Nature, Bacon had to break the fetters of the past. These, in his view, were a Christian tradition which had belied its promise by sinking into resignation; a Greek tradition which had been entangled with Christianity by both the Scholastics and the Neo-Platonists and had made it still more helpless in the face of Nature; a magical and alchemical tradition which had kept alive the dream of a conquest of Nature but was vitiated by imposture, obscurantism and vain-glory; and a rhetorical and literary culture divorced from the manual arts. How Bacon fought and routed these doughty adversaries is a story until recently very imperfectly understood; but it was brilliantly elucidated four years ago by Prof. Paolo Rossi, of Milan, in his "Francesco Bacone: della magia alla scienza". Crowther is not alone among British scholars in ignoring Rossi's book; but he has done so at his peril. It is the only large-scale advance in Baconian studies since Spedding and Ellis.

Crowther's approach is unsystematic and unhistorical. He makes no serious attempt to describe the corpus of Baconian writings, to characterize the items, to date them, or even to list them completely. He does not seek to place them in their context in contemporary European culture. His method is to bring out of the Baconian hat one topic after another, illustrating it by quotation or free paraphrase but never indicating its source. To check him on any point would involve an endless chase. The chief aim of his study is to direct attention to any advance in modern science which can plausibly be regarded as a late flowering of some Baconian seed of thought. This, though not valueless, is a treacherous game. It is not what Pavlov or Sherrington did in the twentieth century that makes Bacon great. It is what Bacon himself did in the seventeenth. This the reader will not find in Crowther's book, for it can only be exhibited against a background which he does not supply.

B. FARRINGTON

BRIDGING THE GAP BETWEEN SCIENCE AND CHRISTIANITY

The Spiritual Crisis of the Scientific Age

By G. D. Yarnold. Pp. 207. (London: George Allen and Unwin, Ltd., 1959. Published for the Sir Halley Stewart Trust.) 18s. net.

BY and large, Mr. Yarnold's book could be described as a dissertation upon the theme of General Smuts's presidential address to the British Association at its centenary meeting, that man's material progress has outstripped his moral and spiritual advance and that advances there are imperative if man is to regain control over events. Dismissing as irrelevant any idea of a conflict between Christianity and science, Mr. Yarnold seeks to indicate what that relationship could be in the modern world and its bearing on the far-reaching crisis, essentially spiritual in character, through which the world is passing, largely because of its inability to assimilate new scientific knowledge and to direct rightly the new technical skills. In effect, the book consists of three essays, the first of which discusses the crisis of understanding which arises in considering the order of Nature, the second the crisis of belief which confronts us in considering scientific presuppositions and some of the central doctrines of the Christian faith, and the third the crisis of living involved in the ethical and moral problems of the nuclear age.

These three aspects are linked by the logical connexion between knowledge, belief and practical activity and the underlying insistence that the danger confronting civilization to-day arises primarily from the refusal to confront spiritual issues. Mr. Yarnold writes reasonably but persuasively. He suggests in his first essay that to bridge the gap between the sciences and Christian theology we need ask no more than the acceptance of three simple integrative principles: the external world is not self-existent, but is created by God; in studying the external world by the method of the sciences, the human mind makes contact with the divine mind—thus discovery and revolution are two aspects of the same encounter; and the fundamental laws of Nature are what they are because God has so ordered the world which He has created. In his second essay he presents his reasons for believing that in its essentials the Christian tradition has been preserved with commendable accuracy, and while he recognizes the difficulties which the modern scientific outlook places in the way of full Christian belief, he himself holds that faith with intelligence as well as with conviction.

Even those who are unable to go all the way with Mr. Yarnold in these interpretations of the world of Nature and of the Christian faith may well agree with him in much that he writes about the crisis of living. No argument as to how far the ethical standards for which he pleads can be truly described as Christian ethics can invalidate a penetrating analysis of the bearing of respect for human personality and the values which characterize the teaching of Christ on the problems of living that arise in the world to-day. The acuteness of such problems is largely due to our failure to notice the human problems created by technology until those problems have become unmanageable. It is not the emergence of entirely new moral problems but the extraordinarily rapid increase in the power which the new knowledge has placed at man's disposal: man's power has outgrown his moral capabilities.

On many of the varied aspects of the problems that arise in this situation Mr. Yarnold writes with insight and sanity, and this essay could well be read with profit by many who might be disinclined to follow him in the two preceding essays. Particularly on the industrial society he is trenchant and displays the critical issues, and on nuclear power and defence he has words which might well be pondered by some of the advocates of unilateral action who are inclined to overlook a government's responsibility to protect the lives and property of its nationals. Mr. Yarnold may not carry all his readers with him in his allegiance to Christianity, but he should at least be sure of their support in the moving appeal of this essay to bring all the moral and spiritual resources at our disposal to combat unprincipled private personal gain and human injustice which to-day technical knowledge and skill have often enabled to flourish on an unprecedented scale. Mr. Yarnold has at the least focused attention on some of the fundamental issues of our time as well as on the relations between the natural sciences and the Christian faith with dignity, sincerity and scholarship.

R. BRIGHTMAN

NEW HORIZONS IN CHEMISTRY*

By Sir ALEXANDER TODD, F.R.S.

ORGANIC chemistry is one of the most remarkable of all the sciences, and is usually regarded by the layman as one of the most abstruse and remote from everyday life and thought. This view is, perhaps, based on its content of jargon and its use of abbreviated molecular formulæ as a kind of hieroglyphic script. It is difficult to believe, however, that a science can properly be described as abstruse which permeates almost every material aspect of modern civilization, which stands as the bridge which links the physical with the biological sciences, and which is, perhaps, the biggest of the sciences in its factual content and in the number of its adherents. Organic chemistry is, perhaps, the most logical of the sciences, and in its history of about 150 years it has suffered fewer theoretical upsets than other sciences. It is a remarkable fact that the whole towering edifice of the subject rests essentially on three basic concepts propounded in the third quarter of the nineteenth century, namely, the concept of fixed combining power of valence due to Frankland, the Kekulé–Couper theory of the tetravalency of carbon and the capacity of carbon atoms to join together into chains and rings, and the theory of the tetrahedral carbon atom due to van't Hoff and Le Bel which gave us stereochemistry. All these concepts were purely empirical, but they have stood the test of time, and on them the whole of modern organic chemistry rests; advances in theory have occurred since they were first enunciated, but these have been essentially refinements giving more precise meaning to them and have in no way upset or destroyed their validity. I doubt whether the same claim could be made of any other science.

There have been two definitions of organic chemistry. Historically, the first, due to Berzelius, was "the chemistry of substances found in living matter". The second, commonly ascribed to Gmelin, appeared first about fifty years later when more was known about the peculiarities of the substances found in living matter and was simply "the chemistry of the carbon compounds". Each of these definitions is valid; but neither is wholly satisfactory, since the first is too restricted and the second is in certain respects too general. A very large number of known carbon compounds are of purely synthetic origin and do not, so far as we are aware, occur in living matter; but it is undoubtedly true that the study of substances which are found in living organisms has provided most of the major stimuli to the advance of organic chemistry throughout its history, and there is little reason to believe that this will not continue to be the case. After all, it was Pasteur's work on the tartaric acids from wine that led to the van't Hoff–Le Bel theory, the anthraquinone dyestuffs stem from Graebe and Liebermann's work on alizarin from madder root, and work on polymerization and plastics goes back to the studies of Harries on natural rubber. Many other examples could be quoted, but I shall mention only one other because it is probably not very well known. It was the work of Windaus on the isomeric sterols that influenced Hückel to develop his theoretical studies on stereoisomerism in fused ring systems and through this developed in the fulness of time a realization of the deep significance of conformational analysis in reduced ring systems—beginning with Hassel and developed by Barton and others—and with it the concept of a new dynamic aspect of stereochemistry which has in recent years exerted a profound influence over a very large area of organic chemistry.

The direct study of substances present in living matter—broadly described as natural products—in the sense of their structural elucidation and total synthesis, has been a dominant feature of organic chemistry only during the twentieth century. That it was not so during the past century can be readily understood, for without an extensive knowledge of carbon chemistry, the relatively complex natural products could not be successfully investigated. The nineteenth century was indeed essentially the period during which the necessary facts of carbon chemistry and the techniques of experiment were developed to the point at which natural product chemistry could be tackled with real prospect of success. This is not to say that natural products were wholly neglected in the nineteenth century; the medical importance of many of them ensured that some attention was paid to them, and, indeed, it was through such work that physiological chemistry and, in due course, biochemistry developed. To-day, with the development of natural product chemistry, it is interesting to see how the demarcation between organic chemistry and biochemistry is again becoming blurred—and with considerable advantage to both sciences.

Not only science as a whole, but also individual sciences, tend to advance irregularly on a broad front, and during any one phase of development there are always individual investigators who stand apart and who break new ground or who see new vistas or horizons not apparent to others at the time. For this reason it is difficult—especially with recent events—to put precise dates to changes in scientific patterns. But in broad terms it seems to me that during the first thirty years or so of the present century most organic chemists dealing with natural products were preoccupied almost entirely with the structure of compounds, while the biochemists were interested essentially with their function. During this period the organic chemists developed their methods of degradation and synthesis to a high degree of perfection and, aided by the introduction of new physical methods of analysis, they have taken them to the point at which the synthesis of molecules as complex as cholesterol, strychnine, chlorophyll, and a number of the coenzymes, has been realized. But since the mid-thirties, slowly at first, but later with increasing rapidity, interest has been moving to a study of structure in relation to function among natural products. It is this which has taken organic chemistry much closer to biology than it has ever been before. Equally, of course, it is the increasing realization that function must be considered in relation to structure that is bringing the biochemists closer to their organic chemical colleagues, to the advantage of both. The way in which organic chemical, biochemical and biophysical studies interact and illumine one another has been one of the

---

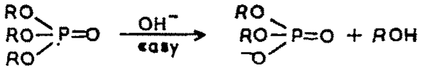
[*] Substance of a Royal Society Tercentenary Lecture delivered on July 20.

features of recent scientific advances in a variety of fields of biological interest, and it seems to me that it might be fitting to try to illustrate some of the new vistas that are opening up by giving a very brief outline of what has been developing in a few fields apparently diverse from a biological point of view, but which have a common chemical thread. It would be possible to choose a series of random topics to illustrate new horizons; but it is perhaps more instructive to choose a small group where the chemical background is common, and I confess that it is also more interesting to me to choose one where the common background is one with which I myself have been associated, namely, the chemistry of the organic phosphates.

It has long been known that organic phosphates are invariable constituents of living organisms and that they have a variety of roles involving energy transfer and the facilitation of both synthetic and degradative processes in biological systems. Just how or why they do so and why phosphate should be found in such complex molecules as, for example, the nucleic acids and phospholipids, has been very much less clear. Until quite recently, organic chemists had paid very little attention to the synthesis or to the study of the chemical behaviour of organic phosphates, and in the absence of knowledge on these points much careful biochemical work remained without a satisfactory explanation.

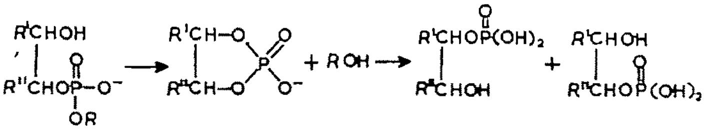
My own interest in this field was aroused just over twenty years ago. I had been introduced to the study of vitamin structure by the late Prof. G. Barger, and this at a time when the relation of several of the B group of vitamins to the so-called nucleotide co-enzymes was emerging and the features which these latter had in common with breakdown products of the nucleic acids was becoming clear. The chemistry of the nucleotides was at this time in a rather rudimentary state and I began a series of investigations aimed at the clarification of this field by synthetic methods, including as a necessary part of it a study of the neglected field of phosphorylation and the study of organic phosphates. Over the years, through the efforts of many devoted and enthusiastic colleagues, we were able to make substantial progress in our general field of endeavour, but I propose to mention here only three features of the work which has been carried out. Each of them is really quite a simple and straightforward piece of phosphate chemistry, but each has a relevance to much wider problems which stand in the forefront of modern organic chemistry and biochemistry. I shall deal with them in turn, endeavouring to show in each instance their importance.

(1) *Hydrolysis of phosphates.* The neutral triesters of phosphoric acid are readily hydrolysed by alkali to the diesters; but the latter are normally resistant to further hydrolysis by alkali, presumably because the formal negative charge on the anion hinders approach of the negative hydroxyl anion to the phosphorus atom.



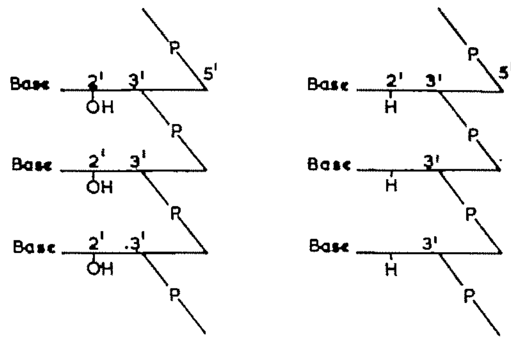
$$(RO)_3P{=}O \xrightarrow[\text{easy}]{OH^-} (RO)_2(^-O)P{=}O + ROH$$

There is, however, one type of phosphodiester which does not show this resistance and which is, indeed, very easily hydrolysed by alkali. The characteristic feature of this type is that one of the esterifying groups bears a *cis*-hydroxyl in the α-position.



In such cases the spatial proximity of the hydroxyl group permits attack on phosphorus despite the negative charge on the anion, and we get very easy hydrolysis *via* a cyclic intermediate, the phosphoric acid residue invariably remaining attached to the glycol residue. Equally, of course, and for the same reason, phosphotriesters containing a *cis*-α-hydroxyl are even more easily hydrolysed than those which do not.

The recognition of these properties of organic phosphates was, in fact, the key to the understanding of the structure of the nucleic acids. The two types of nucleic acid—the ribonucleic acids and the deoxyribonucleic acids—are poly-diesters of phosphoric acid consisting of a large number of nucleosides joined together by phosphodiester linkages. These nucleosides are, in the case of ribonucleic acid, ribosides and, in the case of deoxyribonucleic acid, deoxyribosides, of heterocyclic bases. The conclusion that the nucleic acids are linear polyesters with a recurring 3′ : 5′-internucleotidic linkage, as propounded by Brown and Todd in 1951, rests essentially on their recognition that the behaviour of ribonucleic acid towards hydrolytic agents is that of a phosphodiester containing *cis*-α-hydroxyl groups, whereas deoxyribonucleic acids have the stability of a normal phosphodiester.

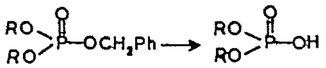


Ribonucleic Acid Deoxyribonucleic Acid

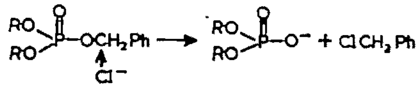
The recognition of the chemical structure of the nucleic acids paved the way for the brilliant biophysical and biochemical achievements of recent years in furthering our understanding of the key position occupied in all living matter by these substances and of the nature of the genes and viruses; and through these achievements there is opening out a wide vista of problems where the organic chemist must play his part—the reasons for specificity in polynucleotides and the determination of nucleotide sequence, the mechanism of protein synthesis and the use of template mechanisms, and the fascinating, if still distant, goal of the synthesis of specific polynucleotides.

Before leaving the subject of hydrolysis of phosphate esters of glycols, it is worthy of note that this same structural feature is characteristic of the phospholipids. Investigations on these important substances based on an understanding of phosphate chemistry by Brown and others is now leading slowly to a clarification of the apparently confused chemical and biochemical literature stemming from earlier investigations.

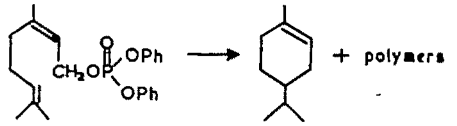
(2) *Anionic debenzylation of phosphates.* In the course of synthetic studies on organic phosphates and polyphosphates it was found necessary at times to be able to remove one benzyl group from a phosphotriester to yield a diester without recourse either to hydrolysis with alkali or acid or to hydrogenolysis, that is, to bring about the simple change:



In such phosphotriesters the CH$_2$ of the benzyl group is strongly electrophilic (electron-deficient), the influence of the phenyl group being reinforced by that of the phosphorus atom. It is thus readily attacked and removed by anions, debenzylation being thereby effected.

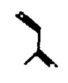


It is not, indeed, necessary to use an actual anion to bring about this reaction, although it is usually convenient to do so in the laboratory. Such compounds as tertiary bases are also effective because of their nucleophilic properties. Nor is the reaction confined to benzyl groups; allyl groups are equally easily removed and, provided that the other two groups *R* in the triester are such (for example, phenyl) as to make the anion $(RO)_2\overset{O}{\overset{\|}{P}}$—O$^-$ very stable, even alkyl groups can be readily removed by anionic fission. An example of considerable interest in connexion with the relevance of these observations to the function of phosphates as biosynthetic intermediates is the observation of my former colleague, Dr. Atherton, that geranyl diphenyl phosphate, in which the nucleophilic olefinic group is, or can be, spatially close to the phosphate group, undergoes cyclization (and also more complex polymerization) with very great ease.

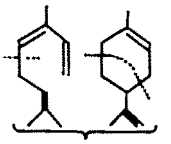


Organic chemists have long been fascinated by the structural relationships between many natural products and have assumed that compounds of one class, for example, terpenoids or alkaloids, are produced in different organisms by essentially similar synthetic processes. Interest in such topics has grown steadily since the early theory of alkaloid biogenesis from amino-acids due to Robinson, and his synthesis of the alkaloid tropinone from simple intermediates in dilute aqueous solution at room temperature under *p*H conditions similar to those commonly obtaining in biological systems. Biogenetic theories of this nature were based on chemical structural relationships and did not purport to set out in detail the precise mechanism of biosynthesis, and it was, perhaps, the failure to realize this which led to their neglect by some biologists and their too uncritical use by some chemists. But properly used, these theories have been, and still are, of immense value in the determination of structure of natural products. During the past twenty years or so the increasing availability of isotopes, both non-radioactive and radioactive, and the development of methods for incorporating them into organic compounds and following the fate of 'labelled' atoms in biological systems, has led to a joint effort by organic chemists and biochemists to elucidate the actual course of biosynthesis of complex molecules in Nature. In this field beautiful work has been carried out by many workers—by Schoenheimer, whose early pioneering work with nitrogen isotopes showed the way, and later by Bloch, Cornforth, Lynen, Shemin, Birch, and others—and in several fields we have now a good deal of precise information available. It should be emphasized that, while this new work has been gradually revealing the course of biosynthetic processes, it has also served to vindicate the organic chemist's use of biogenetic theory in his structural studies. I should like to say something about the mechanism of the biosynthetic pathways to the terpenoid and steroid groups of natural products, since this provides a particularly striking example of the relation between the 'biogenesis' of the organic chemists and 'biosynthesis', and also indicates, again through a consideration of phosphate chemistry, a broad field of further endeavour.

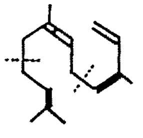
The name terpenoid is applied generally to a large family of natural products of which the simplest members, the terpenes of formula $C_{10}H_{16}$, are common constituents of the essential oils of plants. More complex members include the sesquiterpenes, $C_{15}H_{24}$, the diterpenes, $C_{20}H_{32}$, and the triterpenes, $C_{30}H_{48}$, together with related alcohols, acids, etc. Closely related to them in structure are the carotenoids and the steroids. It was Ruzicka who emphasized the biogenetic relationship of the terpenoids and showed that, so far as their carbon skeleton was concerned, they could, in general, be regarded as made up to 2, 3, 4 or 6 units of isoprene joined most commonly head to tail.



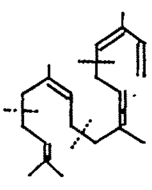
Isoprene



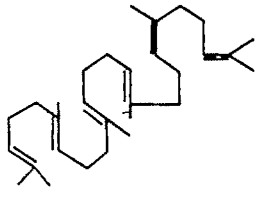
Terpenes



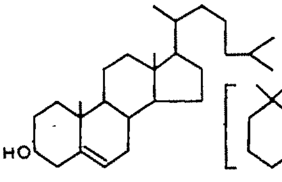
Sesquiterpene



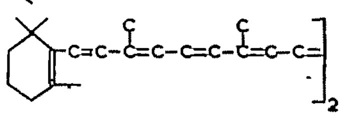
Diterpene



Squalene



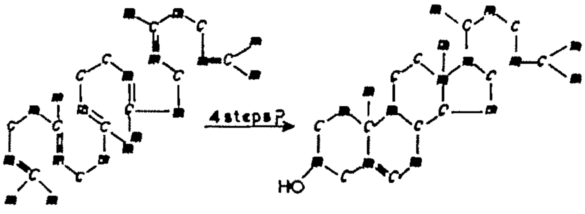
Cholesterol



β-Carotene

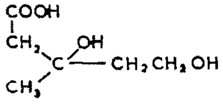
The basis of the isoprene rule can be readily appreciated from the sample formulæ given, and it has been of enormous value in chemical work. The relationship of the steroids to the other terpenoids is, perhaps, not quite so obvious from the formulæ, although it was first postulated just about thirty years ago on biogenetic grounds. The isoprene rule does not purport to portray the biosynthetic mechanism, although it certainly suggests that, even if isoprene itself is unlikely to be the synthetic intermediate in Nature, some closely related substance is likely to be involved.

The unravelling of the actual biosynthetic pathway to the terpenoids and the steroids is one of the outstanding achievements of recent years. True, there are some details still to be clarified; but, thanks largely to the magnificent work of Bloch, Cornforth, Lynen and their colleagues, the general picture is now clear. I do not propose to discuss the development of their work in detail, but will try to give a brief general outline. It really begins with the finding that the cholesterol molecule, and also the triterpene squalene, can be built up in living organisms from acetic acid—this was demonstrated by the administration of isotopically labelled acetic acid and elegant degradative studies on the cholesterol produced. Thus, we know that in the rat the cholesterol produced has the structure shown below, in which *m* represents a carbon atom from the CH_3 group of acetic acid, and *c* a carbon atom from the COOH group. It was next found that squalene is an intermediate in the synthesis of cholesterol, that is, that it is quantitatively converted to cholesterol by the rat. This conversion proceeds in several steps beginning with the formation of lanosterol—although all the intermediate steps have not been unequivocally fixed as yet.

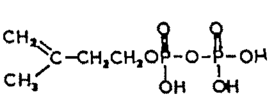


Squalene Cholesterol

So far so good—but what goes on between acetic acid and squalene? What is the hypothetical 'active isoprene unit'? It is now known that acetic acid is first converted in several steps to the six-carbon compound, mevalonic acid, and that this seems to be converted, through its phosphate ester, to *iso*pentenyl pyrophosphate, which has been isolated from biological systems and identified by analysis and synthesis. *Iso*pentenyl pyrophosphate is, in fact, the active isoprene, and from it stem the terpenoids, the steroids, the carotenoid pigments, and rubber.

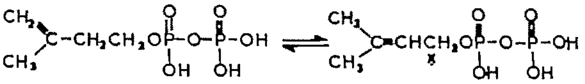


Mevalonic Acid



*Iso*pentenyl Pyrophosphate

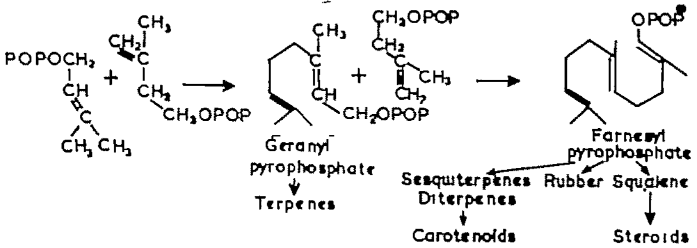
The mechanism of synthesis from *iso*pentenyl pyrophosphate is readily understood from our knowledge of the fission of benzyl and allyl esters of the phosphoric acids by anions and other nucleophilic reagents. *Iso*pentenyl pyrophosphate (I) can, like other similarly constituted compounds, isomerize to ββ-dimethylallyl pyrophosphate (II)—and, indeed, the two isomers may exist in equilibrium.



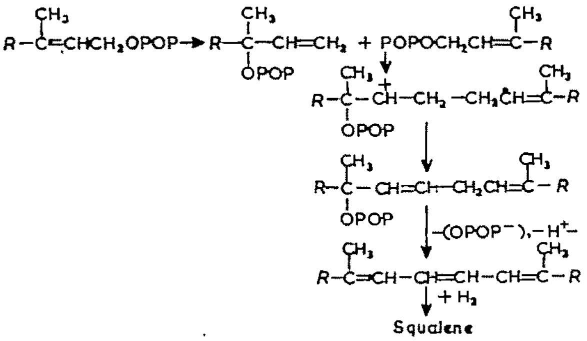
I II

In form II we have an allyl ester capable of attack at the asterisked carbon by a nucleophile (assuming that the ionization of the pyrophosphate residue is sufficiently depressed so that approach of the nucleophile is not inhibited), and in form I the unsaturated *iso*pentenyl group provides a nucleophilic centre. Reaction between the two forms will therefore occur precisely as in the case of geranyl diphenyl phosphate studied by Atherton.

In this way, from two molecules of 'active isoprene' we obtain geranyl pyrophosphate, from this, with another molecule, farnesyl pyrophosphate, and hence, by various routes, the whole range of observed natural products. It should be noted that such intermediates as farnesyl pyrophosphate have, in fact, been isolated and that it is possible, by using an appropriate enzyme system from rubber trees, to make a product indistinguishable from natural rubber starting with synthetic *iso*pentenyl pyrophosphate.

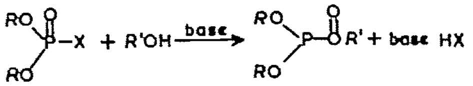


It is noteworthy that the conversion of farnesyl pyrophosphate to squalene involves a doubling of the molecule, since the latter is symmetrical; the same is true of the conversion of the diterpene intermediate to give carotenoids. As has been pointed out by Cornforth, this is readily explained by the so-called farnesol-nerolidol isomerization of the pyrophosphates followed by the same type of nucleophilic fission as before.

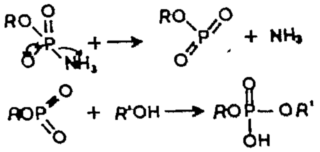


There are still points of detail to be settled in this fascinating story; but the broad picture is there, and from it opens out a new picture of synthetic mechanisms in Nature. Not only can one now begin to picture other biosynthetic processes involving phosphate intermediates, but, as I have already stressed, the essential validity of the biogenetic concepts of the structural chemist receives, through this elegant work, a striking confirmation.

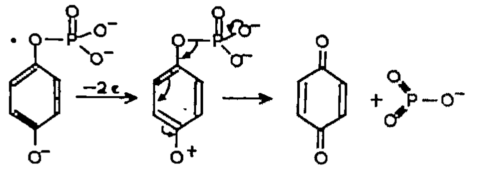
(3) *Oxidative phosphorylation*. Extensive research on the synthesis of phosphates and polyphosphates has led to the development of a variety of phosphorylation methods which fall essentially into two groups. In the first group fall those methods normally based on agents which can be regarded as derived from diesters of phosphoric acid and which proceed by expulsion of an anion.



In methods of the second group, to which some of the most powerful procedures belong, the active agent usually derives from a monoester of phosphoric acid, and instead of an anion a neutral molecule is expelled—for example, in the phosphoramidate carbodi-imide and imidoyl phosphate methods and in oxidative procedures. Much evidence exists for our view that in these cases the active agent in the phosphorylation is the hypothetical monomeric metaphosphate $ROPO_2$, which reacts vigorously with alcohols to give phosphates and with phosphate anions to yield pyrophosphates;

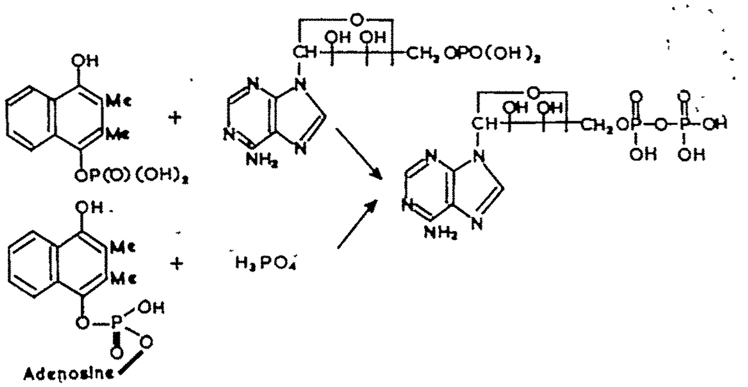


In the case illustrated—the phosphoramidate method—the 'activation' of the reagent is brought about by protonation. But the same effect could be produced by withdrawal of an electron; this is, in fact, the principle of phosphorylation procedures based on oxidation. One in which we have been particularly interested involves quinol phosphates as reagents. Quinol phosphates in presence of oxidizing agents such as bromine, ceric sulphate, or quinones, transfer their phosphate, yielding, at the same time, the corresponding quinone. Thus:

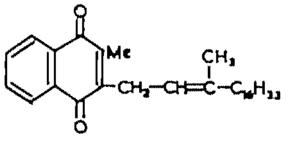


You will notice that we formulate this reaction as producing monomeric metaphosphate. This is supported by a considerable body of evidence. In the first place, the phosphorylation which occurs is a result of the oxidation and is not due to hydrolysis. Quinol phosphates are very resistant to hydrolysis and do not break down in absence of oxygen. Again, although quinol phosphates and their monoesters both undergo this reaction readily with concomitant phosphorylation, quinol phosphate diesters (which cannot yield metaphosphate without hydrolysis) do not, even in presence of reagents as powerful as ceric sulphate. Finally, if quinol phosphates are oxidized in aqueous solution in presence of phosphate anions, phosphorylation occurs to produce pyrophosphate, whereas if oxidized in dimethylformamide in the absence of phosphate considerable amounts of trimeric metaphosphate and only a little pyrophosphate are produced.

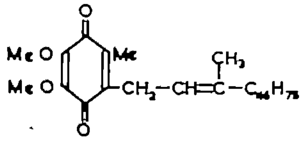
These results are of great interest in connexion with the biological problem of oxidative phosphorylation in the respiratory chain, particularly since, in the laboratory, we have been able to show that, for example, adenosine diphosphate can be synthesized either from a quinol phosphate and adenylic acid, or from a quinol ester of adenylic acid and phosphate anion by bromine oxidation.



It is difficult to believe that there is no connexion between these observations and the occurrence of vitamin K derivatives and the ubiquinones or coenzymes *Q* in systems where oxidative phosphorylation occurs and the participation of which is strongly suggested by available biochemical evidence.



Vitamin K

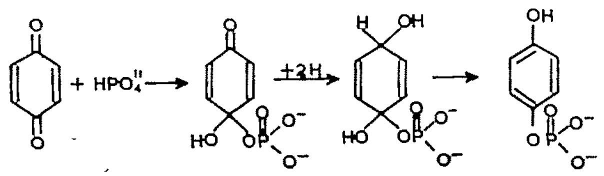


Ubiquinone (Q_{10})

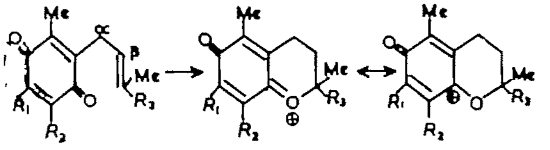
We suggest that these substances are involved in oxidative phosphorylation as the phosphates of their reduced (that is, hydroquinone) forms.

Although this suggestion readily explains the production of adenosine triphosphate through intervention of these natural quinones as their reduced phosphates, there still remains the problem of how these phosphates are produced from the quinones and phosphate anion so that the whole system can work continuously. It is unlikely that reduction of the quinone to the quinol occurs followed by phosphorylation; this could scarcely be done with phosphate anion, and introduction of a 'high energy' phosphorylating entity to bring it about would seem to make the whole process slightly absurd from a biological point of view.

One theoretically possible method would be a simple reductive phosphorylation of the type shown below; but it must be confessed that, despite many attempts, we have as yet been unable to demonstrate any such reaction in benzoquinones or naphthoquinones under many different conditions.



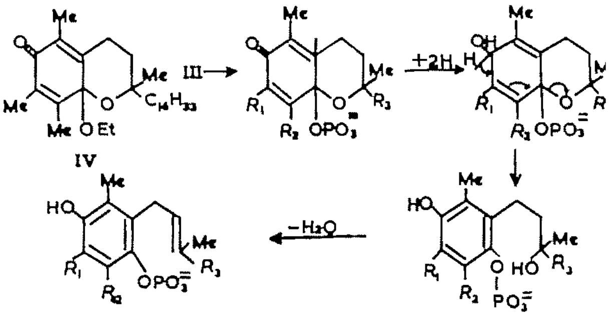
There is, however, another possibility which should be mentioned and which is, indeed, under investigation by Dr. V. M. Clark in Cambridge now. If one examines the structure of vitamin K and the ubiquinones, it is noteworthy that each quinone ring is tetrasubstituted and that each has a trisubstituted double bond in the position β : γ to the quinone ring. If H+ were added to the β-position, a tertiary carbonium ion would be produced which should react with the oxygen of the adjacent carbonyl group to produce the cation III.



III

Evidence for the transient existence of anions of this type already exists in the related vitamin E group, where the substance (IV) has been isolated from oxidation of α-tocopherol with ferric chloride in ethanol. Attack on (III) by phosphate, followed by reduction, should yield the desired quinol phosphate.

If such a scheme can be realized in the laboratory, then it would provide a completely rational picture of the participation of these complex natural quinones in biological oxidative phosphorylation.



I have tried to exemplify, by talking about these aspects of the chemistry of organic phosphates, some of the ways in which advancing organic chemistry is helping at once to clarify certain biological problems and to open up new vistas of potential progress. But I should not like it to be thought that these are the only examples I could have chosen, nor that it is only through the field of biological studies that new vistas are to be found. This is far from true, as could be shown by considering, for example, some of the brilliant recent studies in hydrocarbon transformation and polymerization. But my own research interests have lain largely on the biological side of organic chemistry and I hope, therefore, that I shall be forgiven if I have chosen my illustrations from it.

GEOMAGNETIC STORMS AND THE SPACE AROUND THE EARTH*

By PROF. SYDNEY CHAPMAN, F.R.S.
High Altitude Observatory, Boulder, Colorado

'MAGNETIC storm' is the name long ago given to magnetic disturbance or irregular activity in its more extreme forms. The study of geomagnetic disturbance began in the eighteenth century, with Graham's observations of the compass needle. These were made by eye with a microscope. Eye observation was later improved by use of a moving spot of light on a scale, reflected from a lamp by a mirror attached to a needle. This method made serious demands on the time of the observers, and gave very incomplete information. Yet it was used as late as the first International Polar Year, 1882–83, although in 1846 Airy had introduced photographic observing at Greenwich Observatory. Through the inventions of Gauss, and his influence and that of Humboldt, magnetic observatories for the observation of all three magnetic elements were instituted in increasing numbers from about 1840 onwards. Sabine notably advanced our knowledge of magnetic disturbance by his studies based on the records of the British Colonial Observatories at St. Helena, Toronto and Hobarton. His contribution was largely to the 'morphology' of magnetic disturbance—concerning the distribution and changes of the disturbing magnetic field over the surface of the Earth. Later principal studies in this field were made by Moos in 1910, by Chapman in 1918, and from 1952 onwards by Sugiura and Chapman.

Sabine, Lamont and others contributed also to our knowledge of the time distribution of the occurrence of magnetic disturbance. Soon after Schwabe in 1851 recognized the sunspot cycle, they showed that it is manifested also by magnetic activity. Later, the tendency to a 27-day recurrence was discovered and investigated in different ways, especially by Broun, Maunder, Chree, Stagg and Bartels. It was interpreted as indicating the emission of corpuscular streams from particular areas on the rotating Sun. These streams produce magnetic storms (or less activity) when they impinge on the Earth. Greaves and Newton showed that the greatest storms do not show this tendency towards a 27-day recurrence. They are found to be often associable with solar flares. These are believed to involve the ejection of limited clouds of gas. The time-interval between flares and their associated magnetic storms indicates a speed of travel of the cloud of about 1,000 km./sec. There is some indication that the gas in the continuing streams may travel rather more slowly.

How solar streams and clouds are ejected is still unknown. Scant visual evidence that they are ejected comes from photographs of the edge of the Sun. Solar radio later indicated the rise of gas in the Sun's atmosphere, with speeds that would lead to escape. The streams may be generally invisible because of practically complete ionization of their main constituents, atomic hydrogen and helium. But the hypothesis of causation of magnetic storms by corpuscular flux from the Sun was a reasonable inference without such evidence. Even now the solar sources of corpuscular 'streams' have not been certainly identified.

---

* Substance of three University of London Special Lectures delivered at Queen Mary College during June 1–3.

Birkeland attempted a physical theory of magnetic storms and the associated phenomenon of the aurora polaris. He ascribed them to streams of solar electrons. From model experiments he inferred that the geomagnetic field would deflect them polewards, and that this might account for the existence of the auroral zones and other auroral features. Størmer developed Birkeland's ideas mathematically. He considered almost exclusively the motions of single charged particles influenced only by the geomagnetic field. Schuster and others directed attention to the importance of electrostatic forces between the particles in a stream of charges all of the same sign, such as Birkeland and Størmer contemplated. They urged that such streams could not reach the Earth in sufficient density, because the mutual repulsion of the particles would disperse them widely during their travel.

Størmer did consider the combined action of his particles in one respect, namely, as regards the geomagnetic field caused by the electric current associated with their motion partially surrounding the Earth. He connected this field with the reduction of the Earth's horizontal force during geomagnetic storms. This reduction is one of the most notable features of such storms. Though the suggested electric current was not a complete ring, it came to be linked with the name 'ring current'. The existence of a ring current was postulated by Schmidt on purely geomagnetic evidence, without any proposal as to the location or origin or detailed nature of the ring. Størmer's ring current was not a ring. It was situated far from the Earth (at a distance comparable with that of the Moon). It would greatly alter the field in a manner inconsistent with its own presence there. Further, it could not have the supposed current intensity and yet be composed of charges of one sign only.

Over a period of decades, Størmer studied the paths of single particles in a dipole magnetic field. The intended explanation of auroral phenomena had little success, but his work proved highly valuable in connexion with cosmic rays—a phenomenon unknown when his work began.

Lindemann (later Lord Cherwell) added an important constructive suggestion to a justified destructive criticism of a one-sign stream theory proposed by Chapman in 1918 to explain magnetic storms. The suggestion was that the cause of magnetic storms and auroras is a stream or cloud of neutral but ionized gas. Chapman and Ferraro from 1929 onwards tried with some success to develop an inductive theory of the events that would follow the impact of such gas upon the Earth. In this speculative subject there is natural scope for a variety of views as to the significance of their results. To Hulburt a few years ago they seemed to be "of merely historical interest", whereas according to some other authors the Chapman–Ferraro work has "dominated the discussion" of magnetic storm theory for some decades.

The chief conclusions reached were that the geomagnetic field would 'carve a hollow' in the stream, and that electric currents would flow over the surface of this hollow, mainly on the sunward side of the Earth. These currents shield the volume of the stream from the Earth's magnetic field. Also in the parts of the hollow space nearer the equatorial plane they enhance the Earth's field. This is a notable feature observed at and near the commencement of magnetic storms. Such a current continues as long as the flux, and will vary in intensity with the density and speed of the stream particles. It is conveyed by the different motions of the opposite charges, protons and electrons, near the surface of the hollow. The charges are deflected when they enter the very non-uniform magnetic field in the boundary region bordering on the hollow. The particles are turned back less or more directly, according as their approach is farther from or nearer to the line from the Sun to the centre of the Earth.

Simple approximate relations were found between the first-phase increase of horizontal magnetic force in a storm, the density of kinetic energy of the stream, and its distance of closest approach to the Earth. It became clear that the electromagnetic phenomena that produce magnetic storms and auroras take place within a few Earth radii—of order 3 to 10—from the Earth's centre. This scale is much less than that envisaged in Størmer's theory, or in cosmic rays, which are guided by the Earth's field through a much greater region surrounding the Earth. In a later idealized treatment of a problem on the initial approach of a solar stream, Chapman and Ferraro estimated the limits of density and momentum that determine whether the Størmer simple theory is applicable. They showed that for a stream that can exert any appreciable magnetic effect the mutual influence of opposite charges is important.

They tried also to infer the further, main, development of a magnetic storm, but were unable to overcome the mathematical difficulties involved. They made only a tentative suggestion as to how a ring current could begin to grow. The value of this suggestion is still uncertain. Assuming that in some way a ring current is formed, they studied its stability. They conceived the current as toroidal in form: and the particles, positive and negative, as moving with slightly different speeds around the geomagnetic axis, in planes parallel to the geomagnetic equatorial plane.

In 1957 Singer described a different conception of the motion and distribution of the energetic particles in the space around the Earth—in a region of the scale above mentioned. He pictured the particles as moving around and along the Earth's dipole lines of force, to and fro between mirror points in high latitudes, where they attain their lowest levels. This motion would be combined with a slower drift around the Earth. This drift is eastward for electrons, westward for protons. It seemed obvious that this would supply the inferred westward ring current. This was later proved by Dessler and Parker and by Akasofu, but the cause of the electric current proved to be less obvious than at first appeared.

Singer's conception, and the Chapman–Ferraro scale of the phenomena, were confirmed by the discovery and investigation of the Van Allen belts that surround the Earth. The inner, minor, belt seems to be due to the decay of upward-flying neutrons generated in the Earth's atmosphere by cosmic rays. The outer, major, belt is generally but not universally believed to be fed by the solar streams and clouds. The process by which they are trapped by the Earth's magnetic field is still not clear. The outer belt has been found to vary considerably during the year or two in which it has been studied. U.S.S.R. and U.S. cosmic rockets have confirmed irregularities in the magnetic field in the region of the outer belt, which demonstrate the presence of a ring current.

The particles of the belts are very energetic—of order 100 MeV. for the protons and 600 keV. for the electrons. The density of these protons is extremely low—of order 10^{-4} to 10^{-3} per cm.^{3}. The electrons are more numerous. The protons and electrons are gradually lost, the protons mainly by charge exchange at the lower levels they reach, especially near the mirror points. Thus the continuance of the belts requires continual replacement by new energetic particles.

Although corpuscular theories of magnetic storms and auroras found wide acceptance, they were not without critics and rivals. One of the latter tried to explain the geophysical phenomena by specially intense ultra-violet emissions from the Sun. Inadequacies and counter arguments prevented these theories from making much headway. Corpuscular theories, on the contrary, gained important direct support in 1950 from a spectrum obtained by Meinel of an aurora nearly overhead. It showed lines of atomic hydrogen much displaced towards the ultraviolet. This was interpreted as a Doppler effect indicating the downflow of hydrogen atoms with a speed of order 3,000 km./sec. It was naturally inferred that the atoms reached auroral latitudes as protons—guided by the geomagnetic field—and there gained an electron during their descent through our atmosphere. The speed, 3,000 km./sec., was thrice that deduced from travel-time delays between great flares and their succeeding magnetic storms. The discrepancy had already been noted in another connexion. This was the speed necessary for particles coming from outside, if they were to penetrate to the observed lower levels of auroral luminosity.

Further evidence has since been obtained that both protons and electrons do penetrate to these and indeed to much lower levels. This was first shown in the years 1952–53 by the rockoon studies made by Van Allen and his colleagues in latitudes up to more than 80°. The rockoons, fired in the day-time, carried cosmic ray recorders up to heights of 80 km. or more. In latitudes from about 62° to 75°, they showed that, besides cosmic rays, other less energetic agents added to the record. These agents were later interpreted as X-rays, of average energy about 30 keV. (but running up to 100 keV.). These X-rays were explained as Bremsstrahlungen generated by a small minority of electrons (about 0·1 per cent) in close impact with the nuclei of atmospheric atoms and molecules. The great majority of these electrons were stopped at higher, auroral levels of order 100 km. The flux of electrons appeared to be continual, not confined to great auroral occasions. The rockoon launchings, made in years of moderate solar activity, did not coincide with such occasions.

More recently rocket and balloon studies at night, during notable auroras, have disclosed the entry at such times of protons as well as X-rays generated by electrons. They have been detected down to levels as low as 30 km. during strong overhead auroras, by Winckler and his colleagues. This suggests that at such times electrons and protons enter the atmosphere in special abundance, and with speeds much greater than those inferred by Meinel.

The strongest features of magnetic storms as observed at the Earth's surface are recorded in and near the latitudes where the auroras then occur. These latitudes are below those, 65°–68°, of the 'auroral zone', the zone of most frequent auroral visibility. The magnetic records indicate the presence of strong electric currents along these abnormal auroral latitudes. The intense current is limited laterally, and is therefore called an electrojet. The current circuit is completed mainly in higher latitudes over the polar cap, but also over the great middle belt of the Earth between the northern and southern auroral latitudes. These currents flow in our atmosphere: they are more often westward than eastward, corresponding to 'negative' rather than 'positive' polar magnetic 'bays'. The former occur during late evening to early post-dawn hours, the latter during the afternoon and early post-sunset hours. They and the part of the storm field associated with them seem to develop in impulsive bursts, with quieter intervals between. They are closely associated with striking phases of the aurora during magnetic storms.

The morphology of the aurora is complex. The great increase in visual and instrumental auroral observation during the International Geophysical Year is adding, and will add further, greatly to our knowledge of the extent and changes of the aurora in association with magnetic, solar and other phenomena. At present there is a diversity of theories of the auroral luminosity and the electric currents linked with it. Almost all involve the now proved entry of electrons and protons into our ionosphere from beyond. They come ultimately from the Sun, but some theorists consider that before descent to auroral levels they may spend some time as denizens of the Van Allen belts. Some theories envisage the participation of solar magnetic fields transported from the Sun by the solar streams and clouds. Such fields could hold, among the particles travelling more directly, others of much higher energy and speed, spiralling around the magnetic field lines in the stream or cloud. Hoyle and Dungey attributed importance to two neutral points in the combined geomagnetic and transported solar fields. They suggested that such points may be a means whereby solar particles may enter the atmosphere with added energy and penetration. Other theorists attach importance to atmospheric winds in connexion with auroral luminosity and movements, and with the generation—by dynamo action—of the polar magnetic disturbance currents. Martyn associated the acceleration of particles entering the atmosphere with electrostatic potential differences across the section of a ring current of the type envisaged by Chapman and Ferraro. He also explained the impulsion of the polar disturbance currents by these potential differences, supposed transferred along the lines of force to auroral levels.

A new theory of auroral morphology and of the magnetic disturbance currents, by Akasofu and Chapman, is now nearing partial completion. One novel feature of the theory is the attribution of importance to neutral *lines* in the magnetic field around the Earth. These lines, mainly lying on the night side of the Earth, are associated specially with the combination of the ring current and corpuscular flux fields with the Earth's main field. Subsidiary hypotheses are involved, without present proof, to explain several complicated features of the phenomena observed.

Until recently most auroral and storm theories based on solar streams and clouds ignored the possible permanent presence of gas in interplanetary space and in the region around the Earth where the ring current and corpuscular flux current are believed to flow. The magnetic changes associated with these currents were supposed to be transmitted to the Earth's surface as if *in vacuo*. The radio phenomena of whistlers, elucidated by Eckersley and Storey, indicated the presence of electrons in at least part of the region. Parker for a time concluded that this would almost prevent the fields of the ring current and corpuscular flux current from affecting the Earth's surface field. Controversy with Hines finally led to agreement that this bar to transmission was misconceived. But the transmission will be by hydromagnetic waves rather than purely by electromagnetic waves. Chapman in recent years has inferred that the Sun's coronal atmosphere extends up to and beyond the Earth, and that this interplanetary gas is very hot even up to the Earth's distance. He has further concluded that, if so, the Earth's atmosphere could be enormously more extensive than formerly supposed. This would imply that the Van Allen belts lie relatively low in our atmosphere. But the atmospheric gas in their region, though far more dense than the energetic gas of the belts themselves, would probably be too rare to have much influence on the development of magnetic storms and auroras.

OBITUARIES

Prof. Charles Singer

DR. CHARLES SINGER, the eminent historian of medicine, science and technology, died at his beautiful home, 'Kilmarth', near Par, Cornwall, on June 10, in his eighty-fourth year.

A son of the distinguished Hebrew scholar, the Rev. Simeon Singer, minister of the West End Synagogue, Charles Singer was born in Camberwell, on November 2, 1876, and was educated at the City of London School. At the age of seventeen he became a medical student at University College, London. But the delights of biology were at first too strong, and after a year he turned to the study of zoology and botany under Weldon and F. W. Oliver, respectively. After two years of these studies, he was by a chance invited to enter for a scholarship at Magdalen College, Oxford. His success resulted in his spending three years at that College, studying zoology under Weldon (now transferred to Oxford) and under E. S. Goodrich, for both of whom he retained an immense admiration. In 1899 he graduated B.A. at Oxford, and then returned to London to continue his medical studies at St. Mary's Hospital, Paddington.

Singer qualified M.R.C.S., L.R.C.P. in 1903, and at once departed to Abyssinia as the medical officer to a survey expedition to that country. The result was his first paper (1904) on some unusual clinical conditions. Back in Britain, he filled various resident posts to fit himself for a clinical career, and graduated B.M., B.Ch. at Oxford in 1905. He then had an extensive period in a post in the Government Hospital at Singapore. After his return to England, he became physician to the Dreadnought Hospital and concurrently registrar to the Cancer Hospital in Fulham Road. In the latter post he did much clinical research and laboratory research alone and in collaboration with S. B. Schryver. In 1913 he described a nematode worm in a gastric carcinoma in a rat. He discovered it in the same week in which Fibiger published the researches for which he received a Nobel Prize.

Charles Singer had entered the field of the history of medicine in 1911. He took a prominent part in the early proceedings of the History Section of the Royal Society of Medicine, established in 1912. Osler was its first president, and just before the outbreak of the First World War he offered Singer a post at Oxford, the duties of which were to be mainly historical. Singer's tenure of this post was interrupted by the War, during which he served, mainly at Malta and Salonika, with the rank of captain in the R.A.M.C. But before he was commissioned early in the War he had time to establish, with the help of his wife, Dorothea Waley Singer, whom he had married in 1910, a History of Science Room in the Radcliffe Camera, which is still remembered.

After the War, Singer was invited in 1920 to lecture on the history of medicine at University College, London, and for a short time he continued to hold both the London and the Oxford posts. With his resignation from Oxford there began the most prolific period of his life. In 1930 the University of London conferred on him the title of professor, and he became professor emeritus on his retirement in 1942. In 1930 and again in 1932 he acted as visiting professor at the University of California, Berkeley, where he lectured to enthusiastic audiences. In 1934 he removed his residence to the house near Par, in Cornwall, which was to be his home during the remainder of his long life. Many friends from all over the world remember with pleasure and regret the hospitality so generously extended to them at 'Kilmarth'.

Until he was more than fifty, Singer's interests lay mainly in the history of medicine. In that field he published in rapid sequence several works which opened new ground and led to further study by others. His "Early English Magic and Medicine" (1920) was probably the first serious study of Anglo-Saxon medicine since Cockayne. To the history of anatomy he contributed two important books on medieval anatomical texts (1924–25), and in the latter year there appeared his "Evolution of Anatomy", the substance of his FitzPatrick Lectures. This work was virtually the only history of anatomy in English. The close of this book with Harvey indicated the limit of Singer's serious interest in the history of medicine. Apart from ephemeral writings, none of his original work on the history of medicine dealt with events after the Restoration. He was deeply interested in Greek and Roman medicine, in the medicine of the Dark Ages, and in the history of syphilis. His important paper on the herbal in antiquity was published in 1927. His early medical period closed in 1928 with the publication of his "Short History of Medicine".

Singer's interest in the history of science was at first confined largely to biology and the history of microscopy. The first volume of his "Studies in the History and Method of Science" (1917) contained papers by him which were medical rather than scientific; but the second volume (1921) contained his very important study of Greek biology, and also his paper on the invention of the first optical apparatus. Thereafter he published (1922) his useful little book on "Greek Biology and Greek Medicine". After that, occasional papers on biological and scientific subjects began to appear, and in 1931 he published—as a result of his American lectures—his "Short History of Biology", one of his best books, which he afterwards revised twice.

After this, it was ten years before Singer published another important book. In the intervening period he had spent nearly a year in the United States, had removed to Cornwall, and had written many articles and reviews. He had also played a prominent part in the foundation of the Society for the Protection of Science and Learning, for he was deeply saddened by what happened to European scholars before the outbreak of the Second World War. He had also been reading widely in the literature of science, and the result was his "Short History of Science", published in 1941. This work was much read because it covered the whole field to 1900 within reasonable compass; it introduced a new approach and was easily understood. Towards the end of the War he worked on the "Tabulae anatomicae sex" of Vesalius, and later he completed the philological aspects in collaboration with Prof. Chaim Rabin. This work was published in 1946 as "A Prelude to Modern Science".

In the closing years of the War, Singer was asked by Mr. Derek Spence to write the history of the alum trade; Mr. Spence's well-known firm, dating back to 1855, contributed much to the later history of that trade. For Singer this was a new departure, and he devoted several years of enthusiastic work to this effort. The result was the fine folio volume, "The Earliest Chemical Industry", published in 1948.

Singer next turned to three medical projects which had long been in his mind. The first was the completion, in collaboration with his old friend, Prof. J. H. G. Gratton, of a definitive text of the Anglo-Saxon work known as the "Lacnunga". This work was published in 1952, as also was the second of these projects, a translation of the seventh book of the "Fabrica" of Vesalius.

The need for an authoritative work on the history of technology had long been understood by Singer, and after the publication of his work on the alum trade he devoted much time to the planning of a co-operative work on this subject. The drawing up of these detailed plans for five large volumes must be considered as one of Singer's finest pieces of work. It gave him scope for the use and display of his vast knowledge of men and books, and for the extensive correspondence in which he delighted. Although he had associated editors, chief of whom was the late Dr. E. J. Holmyard, Singer played the main part in the planning and editing of this work. The first volume was published in 1954, and the fourth and fifth volumes in 1958. During its publication he completed and published his last original medical work, his annotated translation of "Galen on Anatomical Procedures" (1956).

In 1922 Singer was awarded a D.Litt. at Oxford for his thesis on the manuscripts dealing with St. Hildegard of Bingen. He already had the Oxford D.M. (1911), and in 1936 that University conferred on him the honorary degree of D.Sc. He became a Fellow of the Royal College of Physicians in 1917. Later in life he became a Fellow of University College, London, an Honorary Fellow of the Royal Society of Medicine, and an Honorary Fellow of his old college, Magdalen, at Oxford. He delivered the L. T. Hobhouse Memorial Trust Lecture in 1951, and the Lloyd Roberts Lecture in 1954. He was president of the History of Medicine Section of the Royal Society of Medicine during 1920–22, and first president of the British Society for the History of Science (1946–48). He was also president of two International Congresses held in London (History of Medicine, 1922; and History of Science, 1931). In 1947 he was president of the International Union for the History of Science. He was awarded the Osler Medal and the George Sarton Medal. In 1953 Singer was the recipient of a large work containing historical essays written in his honour ("Science Medicine and History", 2 vols.; London, 1953).

Singer was by inclination and training a biologist, and to the end of his life he rather regretted that he had not taken up this subject as a profession. When the King's School at Canterbury was evacuated to the west of England early in the Second World War, he was induced to take over the teaching of practical biology. For this purpose he had a room in his house fitted out as a laboratory, and during most of the War he taught in it pupils attending that and another school. It gave him great satisfaction that he consistently obtained a very high standard of passes. In botany, Singer was especially interested in the succulents, and in front of his desk there stood a thriving array of these plants.

Charles Singer will be remembered as much for the encouragement which he gave to others as for his own numerous and important contributions to his subjects. His large correspondence testified to the advice which he gave. But his inspiration and encouragement flowed most easily in his conversation. Those who knew him well appreciated that, despite his learning, his humanity was perhaps the outstanding feature of his character. He had a rich fund of humour, and he could talk simply to the unlearned about subjects which were by no means simple. His studies in the local history and customs of Cornwall were unpublished, and were probably known to very few except his Cornish neighbours.

E. ASHWORTH UNDERWOOD

Dr. Geoffrey Builder

THE sudden death of Geoffrey Builder at the early age of fifty-four has deprived the University of Sydney of an original and sympathetic teacher of physics and Australia of a scientist of international reputation. Born in Western Australia, he was educated at Guildford Grammar School, the Perth Technical College and the University of Western Australia. After graduating in 1928 he joined the Watheroo Magnetic Observatory of the Carnegie Institution of Washington and was responsible for developing a radio technique for the rapid transmission of geophysical data to Washington.

In 1931 Builder commenced work under me at King's College, London, on the exploration of the ionosphere, in which researches he was largely responsible for the discovery of the magneto-ionic splitting of pulse radio echoes and the quantitative verification of ionospheric double refraction which had been predicted by a theory of mine. During July 1932–May 1933 he was a member of the British Radio Expedition to Tromsø, in North Norway, organized by the Royal Society as part of Britain's contribution to the work of the Second International Polar Year. It was this expedition which discovered the phenomenon of the polar radio 'black-out', associated with magnetic storm and auroral activity.

After obtaining the London degree of Ph.D., and becoming a Fellow of the Institute of Physics, Builder joined the Australian Radio Research Board in the latter part of 1933. He then played an important part in developing the Board's new experimental techniques for ionospheric exploration and collaborated with the late A. L. Green in researches on the polarization of long radio waves and on the suppression of fading.

Towards the end of 1934 he joined Amalgamated Wireless (Australasia), Ltd., to take charge of its small group of research laboratories. Under his energetic and skilful direction this group developed rapidly until, at the time of his departure for the Army in 1941, it had grown into an effective organization with more than fifty members of staff. Many well-known Australian radio-physicists and engineers owe their selection and early professional training to the shrewd judgment and scientific and administrative capacity which he exercised during this period as chief of research.

While a major at Army Headquarters during part of the Second World War, Builder acted as adviser on radar, and later engaged in defence production as general manager of Airzone, Ltd. After the War he worked as a consultant and founded two electrical engineering companies. During part of this time he was able to give valuable assistance to the Department of Physics of the University of Sydney in coping with its excessive load of teaching. In 1949 he was appointed to the permanent staff of the Department as a senior lecturer and devoted himself largely to giving lectures on electricity and to the duties of the lecturer-in-charge of second-year physics.

As a member of the Faculty of Science he was very active in proposing various reforms and successful in getting many of them adopted. In recent years he developed an interest in the theory of relativity and gave much time and thought to resolving the famous clock paradox of the special theory. These researches were carried out with his usual thoroughness and acumen and, although at times they brought him into conflict with well-known theoreticians, one of his last papers[1] appears to have settled the controversy by showing that "the clock paradox . . . arose solely out of the elementary mistake of utilizing, in a single calculation, quantities expressed in the measures of two different reference systems". Such versatility and depth are not often found among the younger generation of physicists.

Builder's great interest in the welfare of his students, both collectively and individually, and his exceptional combination of technical, commercial and academic experience made him one of the most successful of teachers and a constant source of wise counsel to his academic colleagues.

EDWARD V. APPLETON

Georges Claude

Avec Georges Claude (décédé le 23 Mai) vient de disparaître un des derniers pionniers, inventeurs. ingénieurs, savants, qui ont permis la révolution industrielle qui précéda la Première Guerre Mondiale. Ingénieur débutant, Georges Claude s'intéresse à l'acétylène, rendu accessible par la fabrication au four électrique du carbure de calcium ; en 1896, il crée l'industrie de l'acétylène dissous et permet l'essor de la soudure autogène, du découpage au chalumeau : les techniques de la construction mécanique sont immédiatement transformées.

Claude se préoccupe alors du prix de revient de l'oxygène, non pas tant pour abaisser le prix de la soudure au chalumeau que pour son application à la production des hautes températures. Avant la fin du siècle dernier, il envisage la possibilité de fabriquer le carbure de calcium dans un four à charbon soufflé à l'oxygène ! Ses efforts sont couronnés de succès et la détente avec travail extérieur, qu'il industrialise dès 1902, est universellement utilisée. En 1910, il démontre dans les aciéries belges d'Ougrée la possibilité d'économies substantielles en sidérurgie par l'emploi de l'oxygène. Depuis la fin de la Deuxième Guerre Mondiale, ses prévisions ont été très largement justifiées ; l'avenir montrera, nous en sommes convaincus, que la production du carbure de calcium au four soufflé à l'oxygène n'était pas davantage une utopie.

Claude s'intéresse également aux gaz rares de l'air et réalise la production industrielle de l'argon, du néon, du krypton et du xénon. L'éclairage à incandescence s'en trouve transformé et ces travaux ont conduit à l'éclairage par fluorescence dont nous jouissons maintenant.

Au cours de la Première Guerre Mondiale, Georges Claude s'attaque à la synthèse de l'ammoniaque ; aux 250 atmosphères du Prof. F. Haber, il oppose audacieusement les 1,000 atmosphères auxquelles il prétend travailler, et il y réussit. Son procédé est encore employé et l'on peut dire que les procédés Casale ou Fauser ne sont qu'un compromis raisonnable entre les pressions déjà courantes du temps de Haber et les hyperpressions dont Claude a rendu possible l'emploi.

Du domaine des hyperpressions, son imagination créatrice entraîne Georges Claude vers l'emploi des pressions réduites. Passionné des grands problèmes qui dominent l'avenir du monde, il voit là un moyen d'utiliser l'inépuisable réservoir d'énergie que constituent les océans par la différence de température entre les couches superficielles et les couches profondes de l'eau. Dans une première installation, il réussit à entraîner une dynamo de 60 kW. par une turbine mue par de la vapeur à faible pression qui se condense au contact d'eau froide. La différence de température n'est que de 20° C. ; l'eau de la Meuse lui sert de source froide, et il prend comme source chaude cette même eau servant à refroidir les tuyères du haut-fourneau.

Georges Claude s'engage alors tout seul dans l'expérimentation industrielle. A Cuba, après trois tentatives, il immerge dans le fond de l'océan un tube de deux mètres de diamètre et de plus de deux mille mètres de long. Il réussit à faire fonctionner son turbogénérateur et peut éclairer la station expérimentale qu'il a construite de ses deniers. Une nouvelle tentative pour atteindre une échelle industrielle (2,000 kW.) échoue par suite de l'hostilité des éléments, déchaînés contre un inventeur génial. La fortune considérable gagnée par Georges Claude ne lui a pas permis de mener à bien, tout seul, l'audacieuse expérience de captation de l'énergie thermique des mers.

---

[1] *Amer. J. Phys.*, 27, 656 (1959).

Le succès de l'opération *Pluto* durant la Deuxième Guerre Mondiale, les projets actuels de pipe-lines traversant la Méditerranée sont le fruit de la tentative de l'inventeur français. Au moment où s'estompent les espoirs trop optimistes fondés sur la conquête rapide de l'énergie nucléaire à bon marché, on ne peut pas s'empêcher d'une certaine mélancolie en considérant qu'un effort beaucoup moins onéreux aurait pu réussir à nous mettre en possession d'une énergie équivalente et ne présentant pas les mêmes dangers.

Avec le recul des années, l'oeuvre de Georges Claude prend tout son relief : il fut, dans toute l'acception du terme, un véritable créateur dont le génie inventif a généreusement servi son pays et la civilisation oxydentale. J. CATHALA

NEWS and VIEWS

Mathematics at Oxford : Dr. Graham Higman, F.R.S.

DR. GRAHAM HIGMAN, who has recently been appointed to the Waynflete chair of pure mathematics in the University of Oxford, in succession to the late Prof. J. H. C. Whitehead, is a Balliol man who, apart from a brief sojourn in Cambridge, has divided his academic life between Oxford and Manchester. After the Second World War, he joined the mathematical staff of the University of Manchester as a founder member of the algebra school which has flourished there since that time. He remained in Manchester until 1955, when he accepted a readership in Oxford. As a pupil of J. H. C. Whitehead, he first worked on a problem of topological origin. In his hands it soon became algebraical, and in the rest of his career he has devoted himself entirely to the 'pure' theory of groups, especially infinite groups. To this theory he has made deep and influential contributions. Lately he has turned his attention to the border country of group-theory and logic, in which he has proved a theorem of great interest on the insolubility of certain group-theoretic problems. Dr. Higman was elected a Fellow of the Royal Society in 1958.

Seismology in New Zealand : Dr. F. F. Evison

DR. F. F. EVISON has been appointed superintendent of the Seismological Observatory, Wellington, New Zealand (Department of Scientific and Industrial Research), in succession to Mr. R. C. Hayes (*Nature*, 187, 24 ; 1960). Dr. Evison was educated at West Christchurch High School and the Victoria University of Wellington, graduating in mathematics and physics. In 1947 he went to the Imperial College of Science and Technology, London, as a research student under Prof. J. McG. Bruckshaw, where he developed the technique of experimental seismology in which a transducer is used for generating seismic pulses in the ground. After returning to New Zealand in 1950 to join the Geophysical Survey, he brought this technique to bear on a variety of seismic propagation problems. He also made a study of deformations of strata in coal-mines. In 1956 the Nuffield Foundation awarded Dr. Evison a Dominion Travelling Fellowship in the Natural Sciences, which took him for a year to the Department of Geodesy and Geophysics, Cambridge. Dr. Evison and his colleagues produced the first geophysical evidence that the Antarctic ice-cap is underlain by a continental crust. They have recently extended the work, which depends on dispersive earthquake waves recorded in Antarctica, to obtain crustal thicknesses over the greater part of Antarctica and the surrounding oceans. The Seismological Observatory, Wellington, operates the Antarctic seismograph stations at Scott Base and Hallett, and also stations at Samoa and Raoul Island, as well as the network within New Zealand itself.

The Russian Earth Satellite 1960λ

A SIGNIFICANT milestone on the road to space flight was passed on August 20, when, for the first time, living animals were successfully brought back to earth after being in orbit in space, aboard the second Russian space-ship satellite. This satellite, which weighed 4,600 kgm., was launched at about 08h. 45m. U.T. on August 19, and entered a nearly circular orbit, inclined at an angle of 65·0° to the equator. Its height varied between 306 km. at perigee and 340 km. at apogee, and the period of revolution was 90·7 min. The satellite, also known as *Sputnik* 5, was designated 1960λ1, and was accompanied in orbit by its final-stage rocket (1960λ2). The living creatures in the satellite included two dogs, 40 mice (21 black and 19 white) and 2 rats ; there were 15 phials containing *Drosophila* and 12 with the alga *Chlorella* ; seeds of maize and many other plants, cancerous cells, and a variety of micro-organisms. The satellite also carried a radio transmitter having a frequency of 19·995 Mc./s., and instruments for measuring the composition of cosmic rays and the intensity of solar X-ray and ultra-violet radiation. It is stated that the pulse and rate of respiration of the dogs were measured and their behaviour observed by television, the information being stored and telemetered back to earth. On the eighteenth revolution of the satellite its velocity was reduced by a retro-rocket and it descended through the atmosphere ; all the animals and biological specimens are reported as being recovered in good condition.

Research and Development in Industry

DR. E. J. SOLVAY'S presidential address to the Society of Chemical Industry at Bristol on July 5 reviews the evolution of the chemical industry, and more particularly the part which research has played in the development of the industry. He also stressed the need for more men in scientific research and for the more effective use of such highly trained man-power (*Chem. and Indust.*, 976 ; July 30). Urging a real co-ordination of research programmes on an international scale as the result of agreement freely negotiated between companies interested in the same activities, Dr. Solvay was thus endorsing a plea which Viscount Chandos had made earlier in the year to the British Electrical Power Convention. Lord Chandos, who delivered the Messel Medal address to the Society of Chemical Industry on May 6 (*Chem. and Indust.*, 1037; August 13), did not in that address renew this plea; but, dealing with research and finance in industry, suggested that statements that research and development effort in Britain are too small are misleading. He put expenditure in Great Britain on research and development in 1959 at about £450 million, of which the Government financed one third of that carried out by private industry; about 27 per cent of the total is in the hands of Government and nationalized industry and performed by them. Lord Chandos believes that more attention should be given to the wider implications of this huge research and development effort. Man's ability to create wealth is increasing much faster than is generally appreciated, and we must be prepared to take some risks to ensure that our means of exchange should increase in a planned and calculated way parallel with the new wealth.

Arctic Institute of North America

THE Arctic Institute is inviting applications from research scientists interested in arctic and subarctic North America and in Antarctica. The aims of the Institute's grant-in-aid programme, which last year numbered thirty-five awards ranging in value from 400 to 10,000 dollars, are to support the work of experienced field-scientists and to introduce other competent researchers to polar science. The Institute favours no particular scientific disciplines, but appraises proposals on their individual merit. Grants are usually made for a one-year period. Opportunities for field research in arctic Alaska and Canada have widened considerably since the International Geophysical Year. The Institute can now assist research workers in obtaining laboratory facilities and field-stations for many kinds of work. For example, the Office of Naval Research's Arctic Research Laboratory at Point Barrow, Alaska, offers laboratory facilities for work in oceanography, sea-ice, ecology, geology and soil science, and arctic climatology. The Institute is establishing this year two stations on Devon Island, N.W.T., for glaciological, marine biological and meteorological studies. Opportunities exist at stations on the Ellesmere Island Ice Shelf and Ice Island *T*-3 for work in glaciology, sea-ice, oceanography, and marine biology. The Institute maintains one small glacier station and is associated with another on the northern slope of Brooks Range in Alaska. The Arctic Institute also invites proposals for support of field-research in Antarctica. Applications must be submitted a full year in advance of an antarctic field-season. Further information about the programme and application forms can be obtained from the Arctic Institute of North America, 3485 University Street, Montreal 2, P.Q., or 1530 P Street N.W., Washington, D.C. Applications for grants for 1961 should be sent in before November 1, 1960.

Boris Kidrich Institute of Nuclear Sciences

VOLUME 10 (March 1960) of the *Bulletin* of the Boris Kidrich Institute of Nuclear Sciences at Vinca, near Belgrade, contains twenty-five articles and one laboratory note contributed by members of the physics, physical chemistry, applied mathematics, electronics and radiobiology laboratories of the Institute. Continuing their work on the development of three basic methods—coincidence, 4π and solid-angle methods—for the absolute measurement of beta activity, V. Urošević and co-workers describe techniques and methods developed for the primary standardization of gold-198. The results obtained agreed with measurements made at Harwell on four gold foils to within the limits of the estimated error (2–6 per cent). New apparatus described include a thorium fission chamber, a low-pressure expansion cloud-chamber, and a high-resolution binary and decade counting unit. Nine papers deal with radiobiological topics. The brief news report included in Volume 10 records that during 1959 more than sixty scientists from other research centres visited the Institute. Eight delegations, including representatives of the International Atomic Energy Agency, Poland, France, the U.S.S.R., Cambodia, United Arab Republics, and Ethiopia, were received. A joint meeting of Polish and Yugoslav physicists to discuss beta- and gamma-spectroscopy was held at the Institute during September, a symposium on analytical chemistry during October and a symposium on solid state physics and chemistry during December. The construction of an experimental reactor of 6·5 MW. (2 per cent enriched uranium and heavy water), delivered by the U.S.S.R. in accordance with an agreement between Yugoslavia and the U.S.S.R., was completed, and the reactor, which first became critical on October 28, began to operate officially on December 28.

Geological Research in the Northern Highlands of Scotland

THE past fifteen years have witnessed active development of geological research in the Northern Highlands, with many younger workers added to those of the pre-war period. The new (third) edition of the "Handbook of Regional Geology" on "Scotland: The Northern Highlands", by Dr. J. Phemister, lists more than 150 references additional to those in the original printing of the second edition in 1948 (H.M.S.O. 5*s*. net). The great majority of these concern detailed researches on the structure, metamorphic history and correlation of the Lewisian and Moine metamorphic rocks; but in view of the active controversies centred on the interpretation of much of this work at the present time, it was not deemed profitable to attempt a complete summary and assessment of it in the present edition. The bulk of the 1948 text is reprinted without modification, additional paragraphs directing attention to more recent publications. By this means the Handbook will serve as a comprehensive and unbiased guide in this field of research until such time as the main controversies are resolved and we can welcome a definitive fourth edition.

National Museum of Wales

THE Department of Zoology at the National Museum of Wales, Cardiff, has recently arranged an exhibit to illustrate the interchange of animal species between Wales and some of the Commonwealth countries. For centuries the Merchant Navy has played an important part in this, for animals of different types such as insects, small mammals and lizards as well as plants have been transferred to new parts of the world. Accidental or deliberate importation has led to a mingling of once characteristic types for any particular country. Thus, the British winter-moth is spreading in Canada, the North American grey squirrel flourishes in Wales and other parts of Great Britain, and the British house sparrow is common in New Zealand. The exhibit at Cardiff is grouped around a model of the old Cardiff-registered cargo vessel *Tredegar Hall* and shows a striking series of insects, spiders, molluscs, reptiles and other creatures accidentally landed at the chief seaports of South Wales from overseas.

Ethionine and Plant Growth Systems

It has already been ascertained that ethionine is an antimetabolite of methionine and that it has growth stimulatory and morphogenetic effects on excised roots of tomato grown in sterile media. R. L. Lowther and W. G. Boll (*Canad. J. Bot.*, 38, 437; 1960) have now reported on the effects of ethionine on six different plant growth systems, for example, growth of lateral buds on decapitated dwarf beans, the rooting of excised, etiolated bean hypocotyls, expansion of leaf disks, and so on. It was noted that the pretreatment of sections of etiolated pea shoots with manganese lowered or prevented the stimulatory effect of ethionine. A considerable amount of new observations on various growth effects is set out in some detail. According to the nature of the growth system, ethionine stimulates the effect of auxins or 'antiauxins'. Some relationships between the known effects of ethionine and theories of auxin action, and its possible significance as an inhibitor of adaptive enzyme synthesis, are indicated.

Translations of Soviet Science into English

The Israel Programme for Scientific Translations has been inaugurated to provide English translations of recent and important Russian books in all branches of science. The programme was initiated by the National Science Foundation, Washington, which supports the programme and selects the material to be translated (Soviet Science in English Catalogue, 1960. Pp. 24. Jerusalem: Program for Science Translations, 1960). The first issue of a catalogue of works translated under this programme lists books which will be available some time before December 1960. The books are photo-offset reproductions of originals typed on IBM electric typewriters and are usually bound in cloth boards with dust jackets.

New Filmstrips

To their series of natural-history filmstrips, Educational Productions, Ltd., of East Ardsley, Wakefield, Yorkshire, has added four more which will be well received by school-teachers. One contains a series of frames describing common plants and animals of the hedgerow and will be specially suitable for junior schools; a second is of the same type but takes its examples from woodlands. The third, "Flowers of the Marsh and Pool", is of more use for botany scholars in secondary schools and includes some of the rarer plants as well as the more common. The fourth strip contains some excellent photographs of British and foreign butterflies and is the forerunner of a similar strip which will deal with moths. Each strip is accompanied by explanatory teaching notes.

Ramsay Memorial Fellowships

The Ramsay Memorial Fellowships Trustees have made the following awards of new fellowships in chemistry for the year 1960–61: Mr. Alan Bewick, a general fellowship at the University of Durham; a Glasgow Fellowship to Dr. D. G. Watson at the University of Cambridge; a New Zealand Fellowship to Mr. G. A. Rodley at University College, London; Spanish Fellowships to Mr. José García Contreras, Miss María Covadonga Rodríguez Pascual and Mr. Salvador Oliver Moscardó, all at Rothamsted Experimental Station; a United States Fellowship to Mr. Herbert L. Strauss at the University of Oxford. The Trustees have renewed the following fellowships for the same year to: Dr. P. J. T. Tait (General Fellowship) at the University of Aberdeen; Dr. W. G. Paterson (Canadian Fellowship) at the University of Oxford; Dr. T. Anno (Japanese Fellowship) at University College, London; Mr. F. Baltá Calleja (Spanish Fellowship) at the University of Bristol.

Announcements

Mr. N. Elson has joined Cossor Communications Co., Ltd., as technical director. Educated at Trinity College, Cambridge, Mr. Elson was employed during the Second World War at the Radar Research Development Establishment, Malvern (formerly the Air Defence Experimental Establishment, Christchurch), where he made notable contributions to the development of the wave-guide. Following a period of research on radio wave propagation at the Cavendish Laboratory and in New Zealand, Mr. Elson was engaged on work on guided weapon systems at Ferranti, Ltd., and has been, for the past six years, in charge of the research and development activities of the Racal Engineering and Instrument Companies as chief scientist.

The Physics of Fluids, published by the American Institute of Physics, 335 East 45 Street, New York 17, N.Y., hitherto published bimonthly, will be published monthly, starting in 1961 with volume 4. It is hoped by this means to speed up publication of research on the structure, statistical mechanics and general physics of gases, liquids, plasmas, and other fluids.

The Chemical Society, London, has issued "Handbook for Chemical Society Authors" (Special Publication No. 14), 6*s*. to Fellows, 21*s*. to non-Fellows (post paid). Although primarily intended for authors preparing material for publication by the Chemical Society, the 224-page well-bound volume contains sections on nomenclature and symbols which are of general interest.

Messrs. Johnson, Matthey and Co., Ltd., Hatton Garden, London, E.C.1, have issued a publication, "Products of the Rare Earth Group", recording the properties of the pure rare earth metals and their oxides. The firm can supply the metals in ingots, rods, and sometimes wires, in various states of purity at much lower cost than hitherto.

A conference on Nuclear Physics is being arranged by the Institute of Physics and the Physical Society and will be held in the Department of Natural Philosophy, University of Glasgow, during September 14 and 15. Sessions will be devoted to electron and photon interactions with nuclei at energies below meson threshold; strange particle physics; interactions involving pi- and mu-mesons; nuclear forces and interactions between lightest nuclei ($A < 4$); experimental techniques. The Rutherford Lecture will be given by Prof. C. F. Powell during the meeting; he will speak on "Studies of Nuclear Disintegrations at Very High Energies".

NEW CHEMICAL LABORATORIES IN THE UNIVERSITY OF SYDNEY

By Prof. R. J. W. LE FEVRE, F.R.S.

CHEMISTRY has been studied in the University of Sydney for 108 years. It began in the early 1850's in basement rooms of what is now the Sydney Grammar School, and was transferred to permanent laboratories in the main buildings of the University as soon as these were ready, about 1858. The foundation professor was the Hon. J. Smith, member of the Legislative Council, who went to Sydney from Aberdeen. Under Archibald Liversidge, Smith's successor, chemistry expanded and moved in 1883 to new premises, to which additions were gradually made through the period 1885–1945. Some details of this history appear in *Chemistry and Industry*, 415 (1951), 736 (1953).

The late Mrs. Brightie Phillips presented to the University of Sydney a sum of £100,000 "on the sole condition that it is to be used for the building of a first wing of a new Chemistry School, and in the hope that it will stimulate other donors". Subsequent grants from the Federal and New South Wales State Governments made the planning of a new building a practical proposition. The late Mr. J. J. Cahill, premier of New South Wales, formally commemorated the beginning of construction by unveiling a plaque on October 18, 1956. The project was completed last year, and chemistry is now installed in its fourth location in the University.

Mr. Cahill's successor in the premiership, the Right Hon. R. J. Heffron, visited the new Chemistry School on June 28, 1960, where he addressed a gathering of University Senate and staff members, benefactors, research workers and senior students, the occasion being "a function to mark the opening of the New Chemistry School".

Mr. Heffron traced the history of the present School from its origins in 1851, spoke in terms of appreciation and congratulation of its development, achievements and status, enlarged on the general importance of chemical industry to the State of New South Wales, and outlined the financial responsibilities which his Government has towards universities and education.

Undergraduate classes were not suspended, and the Premier, with other guests, visited the laboratories where students were working to the normal time-table.

The new building is in a contemporary style, contrasting with the older Victorian Gothic buildings of the University, the earliest of which were the work of the mid-nineteenth century architect, Edmund Blacket. Construction was completed toward the end of 1959; but the building has been progressively occupied as portions were finished. Some 146,000 sq. ft. of floor area are provided. The ultimate cost is about £A.1,500,000.

The plan of the building is roughly 'T'-shaped, lying north-west to south-east. The head of the 'T' is a five-storey block 70 ft. by 240 ft., housing all the undergraduate laboratories, service rooms, stores, boiler room, plant room, compressors, liquid-air machine, etc. The wing seen in Fig. 1 behind the main entrance canopy is largely devoted to research laboratories and staff offices. In line with the front door is another wing containing research laboratories, and leading to the foyers of the lecture theatre block. This contains two lecture theatres, each seating 370, and two others, each seating 170. These, in pairs, are placed back to back, with preparation rooms in between. Store-rooms, undergraduates' reading and

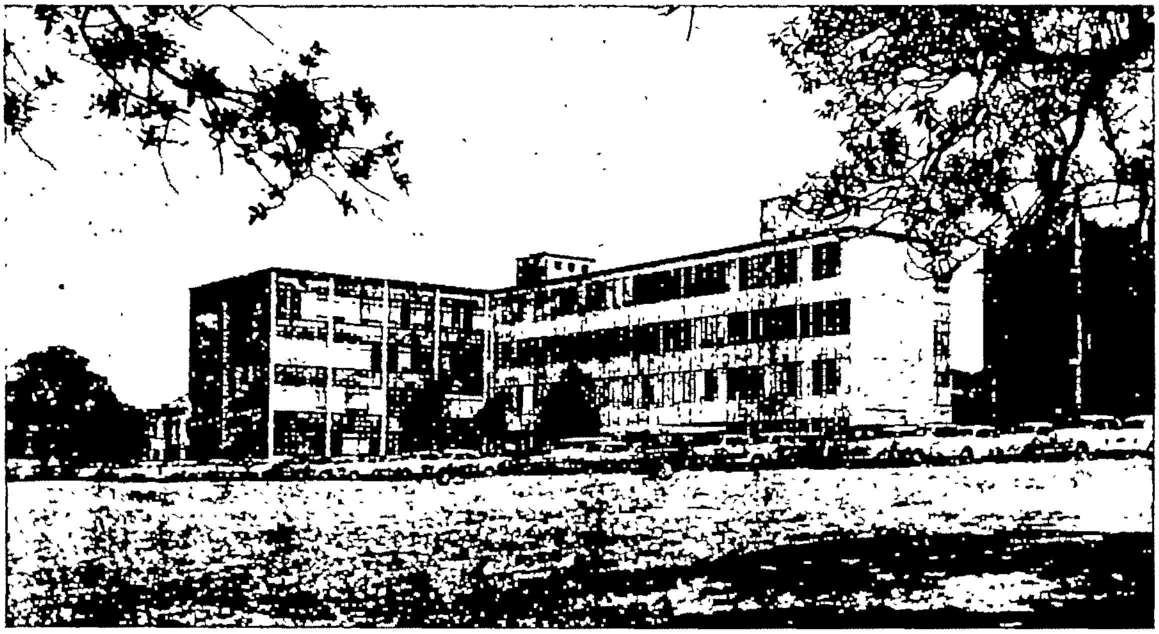


Fig. 1. New chemical laboratories in the University of Sydney as seen from the north

writing room, and a 'kitchen' (making possible the serving of refreshments after public lectures, conferences, etc.) are also in this block. The four theatres themselves are windowless, relying on artificial light and mechanical ventilation.

Features of the building are that all external walls are free of pipes and other extrusions. The roofs slope downwards to the centre lines of each block, along which run a series of vertical ducts containing all rainwater, chemical waste and service pipes, together with fume cupboard and ventilation trunking. Services generally provided include gas, electricity (two- and three-phase a.c. and d.c.), hot and cold water, compressed air, and steam. Outlets for most of these are very generously distributed to ensure maximum future flexibility. Because of the height of the site, water pressure is boosted by compressed air to give a constant 20 lb. per sq. in. on the top floor.

Pleasant features of the completed building are two courtyards to the rear. Here seats have been built and enclose small plots in which shade trees are now being planted. The courtyards are paved with precast concrete slabs, and contain the only explicit luxuries in the whole scheme—two ornamental fountains, and a pair of Italian mosaic tile designs around large supporting pillars, immediately outside the lower lecture theatre block.

Tilden spoke of Liversidge's building as "serving for the present needs of the colony, though in all probability large additions will be necessary before long. About 200 students work in the laboratories . . .". The New Chemistry School in 1960 serves the present needs of some 2,500 undergraduates and about 100 staff and research students. These numbers are expected to increase rapidly; Tilden's remark may soon have to be made again.

PLANT PATHOLOGY IN THE BRITISH COMMONWEALTH

EVERY five years the Commonwealth Mycological Institute organizes a conference on plant diseases which is attended by official delegates from Commonwealth countries, observers from such bodies as the Food and Agriculture Organization, and invited visitors. Similar conferences on insect pests of plants are arranged by the Commonwealth Entomological Institute, the sister institute within the Commonwealth Agricultural Bureaux. This year the two conferences were held in succeeding weeks, and the final day of the Seventh Commonwealth Entomological Conference was devoted to two joint sessions at which agricultural entomologists and plant pathologists discussed topics of common interest. In the morning, developments in the study of plant viruses and their insect vectors with special reference to their bearing on control were considered, and in the afternoon the link between research work and its application in the field of plant protection was reviewed in a series of papers from Canada, the United Kingdom, Kenya and Nigeria.

On the evening of the same day the delegates to the two conferences attended a reception given by the Government at Lancaster House, where they were received and addressed by Lord Hailsham, Minister for Science.

The Sixth Commonwealth Mycological Conference was opened by A. Perera, of Ceylon, chairman of the Executive Council of the Commonwealth Agricultural Bureaux, at the London School of Hygiene and Tropical Medicine, on the morning of July 15, and this was followed by the first plenary session, at which J. C. F. Hopkins, director of the Commonwealth Mycological Institute, reported on the work of the Institute since the previous Conference, a period of expansion marked by the occupation in 1955 of a spacious new building, increase in staff, and an extension of the services offered to plant pathologists and others.

One duty of the delegates is always to review the working of the Institute and to make such recommendations as they may think fit for the next quinquennium. To aid them in this task, and to lay a foundation for their next day's visitation to the Institute at Kew, the papers given during the remainder of the first day dealt largely with different aspects of the Institute's activities.

The primary function of the Institute was to provide an information service, and its main abstract journal, the ***Review of Applied Mycology***, which surveys the world literature on plant pathology, is now in its thirty-ninth year. The exact size and extent of the literature of plant pathology are uncertain. The annual output is perhaps 5,000 items derived over the years from 2,000 current publications, but many of these items are popular and ephemeral. The 3,070 abstracts in the 1958 volume of the *Review* came from 530 different journals, 59 books, and 71 reports—a total of 660 publications—and an analysis of a series of volumes since 1925 suggested that while the scatter of papers is broadening more papers are being noticed from a few major journals. Similarly, the language scatter is on the increase, but while the proportion in French is definitely on the decline, that in Japanese, Chinese, and especially Russian is on the increase; the amount in English now stands at 60 per cent, to which another 10 per cent can be added for papers in languages other than English which have English summaries. With regard to types of disease, the number of papers on bacterial diseases is on the increase but their proportion (5 per cent) seems to be slightly less than it was; those on virus diseases have increased from 6 per cent in 1925 to 18 per cent in 1958. Papers on fungal infections have remained remarkably constant for the past thirty years at about 60 per cent of the total, and thus account for the importance of the Institute's identification service and the help it gives in cataloguing fungi from different parts of the world, especially the tropics. During 1958–59, some 4,000 identifications were made and the Institute's herbarium (Herb.I.M.I.) now comprises more than eighty thousand specimens. There are, however, still many taxonomic uncertainties, and M. B. Ellis, the Institute's chief mycologist, emphasized the benefits which accrue from working visits of both experienced and less experienced taxonomists to each others' herbaria. The herbarium is supplemented or complemented by a collection of living cultures which constitutes the main section of the United Kingdom national collection of fungi, and the curator, H. A. Dade, indicated some of the collection's many contacts and uses. The most recent addition to the Institute's resources is a bacteriological laboratory for the study of plant pathogenic bacteria.

Two-thirds of the world's population is undernourished. The losses of crops from disease are immense. According to E. Hainsworth, preventable losses from crop diseases in Kenya account for one-tenth of the entire agricultural output. In other words, he estimated that one quarter of this loss could be economically prevented by spraying or dusting with fungicides, one quarter by the use of disease-resistant plant varieties, and rather more than one half by the use of seed dressings and the preplanting treatment of seeds. For other diseases no control measures may be available, or the increase in costs from applying an efficacious control would not be commensurate with the increased monetary value of the crop. For example, as J. W. Blencowe and A. L. Wharton of the West African Cocoa Research Institute indicated, though the absolute loss of crop of cacao caused by black pod disease (*Phytophthora palmivora*) in southern Ghana and Ashanti is of the order of 23 and 16 per cent, respectively, and must represent a cash loss of several million pounds, the application of fungicidal sprays is not at present economically justified. The economics of control are, however, under experimental study.

Such data offered to the Conference give clues to modern trends in plant pathology. Up to the First World War may be considered to have been the age of the pathogen. Plant pathology was undertaken by mycologists. Emphasis then shifted to the diseased plant both in relation to the pathogen and the totality of the environment, physical, social, and economic. Plant pathology became a profession. In human medicine, increasing attention is being paid to public health, to the prevention rather than to the cure of disease, and it now seems that this attitude is also gaining ground among plant pathologists. It may be recalled that just over a century ago the Rev. Miles Joseph Berkeley, one of the founders of plant pathology, began his famous series of articles on vegetable pathology in the *Gardeners' Chronicle* with an account of the plant in a state of health. The wheel is turning full circle.

During three days of the reading of papers, some thirty contributions were made by nearly forty different authors on half a dozen main topics, all of current interest.

Throughout the world, and in diverse crops, root rots are being intensively studied. Losses in annual crops can be serious, but the problem of root rots in plantation crops and in forest trees is in many countries particularly acute. I. A. S. Gibson and N. A. Goodchild dealt with *Armillaria mellea* root rot of tea in Kenya, a paper by A. Riggenbach covered white root disease (caused by *Fomes lignosus*) and its control in *Hevea* rubber in Ceylon and R. A. Fox reported on the same disease in Malaya. These tropical examples were followed by a review by J. S. Murray (Forestry Commission) of the increasingly serious depredations caused by *Fomes annosus* among conifers in the United Kingdom. Two further papers, by D. A. Perry (Empire Cotton Growing Corporation) on a *Fusarium* wilt of cotton in Uganda and by C. D. Blake on a banana root rot in New South Wales, provided interesting examples of root rot complexes in the etiology of which nematodes play an important part; successful control of the banana disease being by disinfesting planting material by hot-water treatment and planting in virgin areas or areas which have not carried bananas for at least five years. Such results, and the recognition of nematodes as vectors of some plant viruses, led to resolutions being adopted at the final plenary session for increased emphasis not only on investigations of root rots but also on studies of nematodes, and the desirability of including an introduction to nematology in the training of plant pathologists.

Seed pathology and seed-health testing were comprehensively reviewed at another session by Mary Noble (Scotland), P. Neergaard (Denmark), and J. de Tempe (Netherlands), the three authors of an annotated list of seed-borne pathogens prepared on behalf of the International Seed Testing Association and published by the Commonwealth Mycological Institute in 1958. All concerned with plant introductions are now aware of the extreme importance of being able to rely on any certificates of freedom of 'seed' from disease or disease-inducing organisms which the export or import regulations of their own or other countries may require, but much still remains to be done in devising reliable tests and in ensuring uniformity in their use. These papers and the discussion which followed resulted in another Conference resolution urging the improvement of seed certification schemes, and the production of seed in areas where the incidence of potentially dangerous seed-borne diseases is at a minimum—a resolution particularly appropriate to the eve of the forthcoming 'World Seed Year' being sponsored by the Food and Agriculture Organization.

The elucidation of epidemiological problems in connexion with plant diseases is dependent on reliable procedures for assessing their incidence, so that data obtained by different observers in different areas at different times shall be comparable. Further, rational and economical control measures are also often dependent on the forecasting of disease outbreaks. E. C. Large (United Kingdom Ministry of Agriculture's Plant Pathology Laboratory) gave a lucid survey of these aspects of the annual outbreaks of potato blight in England during the past twenty years where, due to the close co-operation between the meteorological service and the Ministry, the conditions which determine the progress and severity of potato blight are now better understood than in any other country, and regional forecasting is becoming increasingly accurate. In another interesting paper, L. Ogilvie and I. G. Thorpe (United Kingdom) outlined the co-operative investigation in Western Europe and North Africa of the annual spread of black rust of wheat (*Puccinia graminis*), outbreaks of which in the south and west of England in mid- to late summer have been shown to originate in North Africa in the early spring. At another session, breeding for rust resistance was reviewed in papers from the United Kingdom and New South Wales.

Virus diseases, diseases of various tropical crops, and fungicides were dealt with in a further series of papers and discussions. During the Conference a whole-day visit was made to the John Innes Institute on the occasion of the British Mycological Society's annual plant pathology field meeting, and during the week after the conference opportunities were made for the delegates to visit a number of research stations and laboratories.

G. C. Ainsworth

INTRACELLULAR LOCALIZATION OF ENZYMES

A COLLOQUIUM on "Intracellular Localization of Enzymes" was held in Louvain on June 17–18 under the auspices of the Centre Interuniversitaire de Recherches Enzymologiques. The meeting was organized in a similar fashion to that held last year by the same centre on "Specificity in Protein Biogenesis" (see *Nature*, 184, 1198; 1959). A limited number of papers were read by invited speakers and plenty of time was allowed for discussion. In order to favour an informal exchange of ideas, it was decided not to publish the proceedings of the colloquium. The interest of the meeting was enhanced by the participation of a number of foreign guests to an international symposium organized earlier in the week at the Cancer Institute of Louvain, under the Cell Biology Programme of Unesco, on the subject of "Cell Biology and Growth Inhibition". In addition, the sessions were attended by more than a hundred workers from various Belgian laboratories and by a few visitors from abroad.

The meeting was opened by A. Claude (Brussels), who gave an account of the history of cell fractionation and reported his own recent electron-microscope observations on the cytoplasmic granules of kidney tubules. In the past few years, non-mitochondrial granules have been described under a variety of names in a number of different tissues. Their main characteristic is that they are limited by a single membrane and do not contain cristæ, but their size and internal structure may vary considerably from one tissue to the other and even within the same tissue. Claude proposed the general name of 'cytosomes' for these organelles, and put forward the hypothesis that they may represent various functional states of the same entity, possibly related to lysosomes.

The same theme was discussed later by other speakers, namely, S. J. Holt (London), A. B. Novikoff (New York) and H. Beaufay (Louvain). With respect to liver tissue, the two former speakers both showed excellent evidence, based upon cytochemical staining results and further supported by electron-microscope observations, indicating that acid phosphatase is essentially localized within granules arranged along the bile canaliculi, and previously described under the name of peribiliary or pericanalicular dense bodies. Beaufay reported on recent experimental results obtained with several density-gradient centrifugal systems of high resolution and confirming the association of acid phosphatase with numerous other acid hydrolases, as embodied in the lysosome concept. In agreement with the other speakers, he found numerous pericanalicular dense bodies in purified preparations of lysosomes. However, these preparations also contain a second biochemical component, namely, the granules containing uricase, catalase and D-amino-acid oxidase, which are different from lysosomes, as well as a second morphological component, the so-called 'microbodies', which differ from the pericanalicular dense bodies by the absence of ferritin-like grains and the presence of an internal multi-membranous or crystalloid core. Beaufay suggested that these microbodies might represent the uricase-bearing granules, which are known to contain little or no iron. But evidence to the contrary was produced by Novikoff, who found that the liver of rats injected with bilirubin becomes loaded very rapidly with granules containing acid phosphatase as well as with typical microbodies, which appear to be positive for acid phosphatase in a cytochemical staining test adapted to the electron microscope. It was decided that this point required further elucidation.

A serious discrepancy between biochemical and cytochemical staining results was discussed in detail by Holt, who showed that in fixed rat liver, kidney and several other tissues, esterase, an enzyme known to sediment quantitatively with the microsomes in liver homogenates, shows exactly the same localization as acid phosphatase when revealed by staining techniques. It was also shown, however, that esterase is removed selectively from sections of unfixed frozen-dried tissues by immersion in isotonic sucrose. The possibility thus exists that esterase may be loosely attached to the surface of lysosomes in the cells and be eluted from this site and secondarily adsorbed on the microsomes upon homogenization.

A great deal of attention was also paid to the role of lysosomes in cytolysis and in the accumulation of waste products, as well as to their relationship with pinocytosis vacuoles or phagosomes. Novikoff produced evidence, based on the simultaneous histochemical detection of acid phosphatase and of foreign material taken up by cells, as well as on electron-microscope observations, which strongly suggests that lysosomes may be involved in all these processes. Beaufay reported the results of experiments of P. Jacques, in which the biochemical properties of lysosomes and phagosomes were found to be very similar in many respects, though not identical. In the discussion which followed, it was agreed that the uptake of foreign material by engulfing processes may be followed by intracellular digestion and even possibly excretion of residues, and that a number of the vacuoles and bodies observed morphologically as well as the phagosomes and lysosomes may be part of a general system involved in these phenomena. The exact identification of the granules implicated and of their role will, however, require a great deal of additional work. This session was closed by the presentation of a remarkable film on pinocytosis in tissue cultures by H. Lettré (Heidelberg).

The necessity for correlating biochemical results with accurate cytological data was emphasized by C. Allard (Montreal), who showed that feeding azo-dyes to rats causes striking changes in the cellular composition of the liver. Bile duct and connective tissue cells proliferate considerably while the proportion of parenchymal cells decreases. Allard reported further that homogenates originating almost exclusively from parenchymal cells can be prepared at all stages of this transformation by pressing the liver through a mesh which retains the connective, vascular and ductular framework of the organ. Enzymic studies performed on these homogenates

BRITISH ASSOCIATION MEETING IN CARDIFF

THE TWO ASPECTS OF SCIENCE*

By Sir GEORGE THOMSON, F.R.S.

President of the British Association

SCIENCE is already valued for what it can do to increase man's control over Nature, and feared for what some of its consequences may be. Some would have us consider these consequences as the sole justification of science. This view, or something very like it, is the official attitude in Marxist countries, and there are many in Great Britain and in the United States who would be horrified to be told they were Marxists but who without any explicit statement do in fact act and speak as if they thought the same. But this view is too limited. There is a second aspect; it is this.

Science aims at understanding the nature of things: in this it is at one with religion and philosophy. But its approach is the opposite. These last try to gain knowledge of the whole, in one case by an awareness of the Deity, intuitive or revealed, in the other by building with words a system of thought which can account for fundamentals. Science starts from the other end. It begins by studying details, often apparently trivial details but things which are queer and appeal to human curiosity. Things like black rocks which attract iron or rubbed amber which makes chaff fly.

This has been more successful than one could have expected. It is a method difficult to defend *a priori*—it has often been made fun of. Swift ridiculed the philosophers of Laputa who studied how to make sunshine from cucumbers. But the method works.

From the study of details such as these come *concepts*. These concepts, or some of them, show vitality and take charge, as characters in fiction are said by authors to do. They are the bases for hypotheses and 'laws', they are the things that get names—mass, energy, temperature, entropy, wave-length, charge, electrons, quantum numbers, to take some examples from my own subject.

Some do not survive: caloric, phlogiston. Others are deposed from their independence and become vassals of the more successful, as mass has of energy or valency of electronic structure.

But the successful concepts—or the best of them—are not concerned with details any more; they penetrate deep in the heart of things. Electrons, for example, are regarded as present in all ordinary matter, and in any attempt to explain the behaviour of matter, physical, chemical or ultimately biological, one is, if one goes deep enough, forced back on to them. At present they stand as a fundamental concept, but even if, as is quite possible, they ultimately come under some still more general idea, the concept of an electron will still be used, as mass is in mechanics.

It unifies our thoughts over a vast area of facts. Thus there is excellent reason for believing that the whole of chemistry is explicable in terms of electrons and the wave functions which describe their location. This is an enormous simplification of thought, even if the mathematics are too difficult to work out in most cases. It does not much matter from this point of view that test-tubes are cheaper than electronic computers if you really want to know the answer to a practical question.

Scientific concepts enable certain aspects of the enormous complexity of the world to be handled by men's minds. They are suggested mostly by experiment but partly by mathematics, and controlled by the need that they should not lead to illogical consequences.

These concepts represent an extension of the human intelligence. They are not easy; many have subtleties which, for example, oblige the popularizer to take anxious care lest in trying to simplify he make statements which are simply untrue. Some are more fundamental than others, but even those which turn out to be only rough pictures of what really happens often retain their usefulness. They are sketches as compared with finished pictures, and if details are not needed a sketch is often clearer.

Concepts are discoveries as well as, indeed more than, inventions. They have more in common with the discovery of America than with the invention of the spinning jenny or of the electronic computer. Some at least have been forced on unwilling minds by hard facts and have resisted many attempts to displace them. I am thinking more especially of the quantum theory.

Not merely are they an exercise of the human mind which equals the brilliance of any system of thought, philosophical or even mathematical, but they represent reality.

The nature of the relationship is to me a mystery, but they are certainly not merely the product of the human mind.

---

* Presidential Address delivered in Cardiff on August 31 and published in the September issue of *The Advancement of Science*.

Science is a pyramid based on many varied facts, topped with a crown of ideas reaching to the skies. These are its fruit but can change without affecting its stability. I sometimes think that in philosophy the pyramid is the other way up!

What we want as scientists—I am sure in this I speak for the great majority—is that the world should realize that we are not interested merely in making possible new drugs, television sets, or weapons, though all these are important, but in enlarging the bounds of human knowledge.

The greatness of the human race is indeed many-sided. Thus in the world of art there is a difference between the ability to compose or interpret a great piece of music and that which makes possible a great novel or a great picture. Yet all are evidence of greatness and worthy of the name. Still more so is moral greatness. "There is one glory of the sun and another glory of the moon and another glory of the stars."

I have no desire to exalt our profession unduly, but surely the ability to understand, even to a limited extent, the world around him is one of the powers of which man has good right to be proud. Indeed it seems to be the one which most divides him from the animals. The lark's song, the heroism of a plover luring an enemy away from her young, the cat who was seen to attack a grizzly in defence of her kittens—these, if taken at their face value, are notable even by human standards, but I am not aware (though I speak with great diffidence) of any creature which even appears to be trying to discover any general principles.

The chance of understanding things of fundamental and permanent importance is what makes the pursuit of science fascinating and worth while.

These two aspects of science do not in fact conflict. The best way to make advances in technology, whether on the medical or the engineering side, turns out to be to understand the principles. This is quite a recent discovery—indeed it has probably only recently become true. It would not have been much use, for example, to man in the stone age, or even a few hundred years ago, to try to understand the principles of tanning with no basic knowledge of chemistry to guide him. He did better by trial and error. Even the steam engine was developed with little knowledge of the determining principles, though the best scientific minds of the day were much interested, and the thought they gave it advanced science by discovering thermodynamics.

Electrical engineering was the first important activity to be developed from the start on scientific principles, and even here Edison did great things on a decidedly sketchy knowledge. But increasingly more discoveries are made in research laboratories and fewer by workmen on the bench. This is what one might expect. As fundamental principles get known it is possible to use their consequences intelligently. Often these consequences are too complicated to be calculated, but knowledge of the principles is an enormous help by showing in a general way what is likely to happen.

Then of course there are the modern technologies which derive directly from some important new basic discovery, such as electronics and nuclear energy.

This dependence of technology on pure science is now pretty generally recognized by industry. The more progressive industries maintain research laboratories which both make use of the basic discoveries made in the universities and elsewhere, and contribute their own. These laboratories may be owned and operated by individual firms, or be co-operative efforts of an industry in the form of research associations substantially helped by Government. There are black spots of course—industries which spend too little on research or organize it badly—but broadly speaking the need is realized and reasonably well met.

Pure science receives a great return for what it contributes to technology, and this in two ways, materially and in the realm of ideas. Consider first the material return; a modern physics laboratory could not work without instruments developed for technology and obtainable cheaply because industry needs them in large numbers. Take just two examples out of many. The use of high vacua—and how important this is—has been enormously facilitated by the needs first of the electric light industry and then of the manufacturers of radio valves. Again, the complicated electronic devices which crowd every physics research laboratory would be impossible without the cheap components of all kinds manufactured originally for radio and now for television. For this return by industry I sometimes think we academic scientists are not as grateful as we ought to be.

The other influence of technology is more subtle but as important. As science advances, concepts tend to become more and more abstract, further from anything that can literally be touched or handled. To take a simple case, energy is more abstract than mass which it replaces. In the higher flights of theoretical physics abstraction goes much further. Is there not a danger that one may lose touch with reality, and end up by supposing that some elaborate piece of mathematics represents reality when it is only a creation of the mind, inspired indeed by physical reality but no more like it than is a modern picture? I think we are safe so long as the people who make these theories are reasonably close to those who use them, not merely in laboratories but also in industry.

A theory which involves detailed consideration of the behaviour of particles less than a millionth of a millionth of an inch across would have seemed to Swift too absurd to be even worth ridicule. Yet one cannot regard it as a pipe dream when it leads to the great reactors of Calder Hall or Chapelcross. To me, the most amazing thing about science, and the most surprising and exciting fact about our world, is this astonishing connexion between highly abstruse theoretical ideas and the matter of fact, in this case the housewife boiling her kettle with power from nuclei. This surely adds an immense thrill to discovery. I have no sympathy with those who regard technology as intellectually a poor relation of science. To me science without technology is incomplete and inconclusive. Systems of philosophy come and go; some are perhaps true but who can tell? But when conclusions deduced from precise experiments by mathematical theory lead to detailed predictions from which working machines can be designed, machines which without the theory no one would have thought of in a million years, then indeed one knows that one lives in a universe which is rational, and that one has found the key to one of its rooms.

In speaking to you to stress the importance of the idealistic—almost the spiritual—side of science, I am hoping that my words may reach others not here who are brought less closely into contact with it than are most of you.

May I remind you of a few of the ways in which scientific knowledge has influenced and is influencing thought and the intellectual climate of the world? First and most obvious is the idea of evolution, that things change consistently and pass through successive stages, whether they are mice or stars. That living creatures in particular not only go through individual changes, but also that in the flow of generations changes come over the race, or over a part of it, and that these changes lead to profound differences like those which distinguish men from molluscs. In the year of the centenary of the "Origin of Species" just past, you have heard the profound consequences of this idea described much better than I can.

In the course of my life the quantum theory has produced a revolution in physics comparable with that produced in biology by Darwin. We have been forced, some of us very unwillingly, to believe that at bottom the laws of physics are not statements of what *must* happen, but of the relative chances of a variety of alternatives. That the determinism of the planets, for example, occurs merely because planets are enormous on the atomic scale and their distance from the Sun very large, and that the "Nautical Almanack" would be impossible if the solar system was reduced to the scale of a molecule. Certainty comes with a massive body; or if the bodies are small, one must have very many of them so that the laws of statistics can manufacture near certainty out of highly uncertain events, as they do in life insurance.

This makes quite a difference to the way one regards the world, and I think its consequences are still not realized by the average educated man, though it has been accepted by the majority of physicists for thirty years. It shows for one thing how dangerous it is to extrapolate, to attribute—in this case—to the very small the kind of behaviour that is common sense when one talks of objects of large or ordinary size. That, for example, if a particle crosses a flat screen with two holes in it, it must have gone through one to the exclusion of the other. This is not true of an electron.

The quantum theory stresses another point which is fundamental to the modern view of physics—the importance of the observer. An experiment to be of any use must be observed. True, the immediate observer may be a photographic plate which forms a latent image to be developed and examined later, but there must be something. In other words, the scientist can only learn about the world through his senses. Theories are meant to unify sensations and in this sense explain them, but on these sensations they ultimately rest.

The observer first received proper attention in the theory of relativity. So long as there was supposed to be an aether, there was a privileged observer, or class of observers, those at rest with respect to it. Without it all are on the same footing, and equally entitled to be considered. Now relativity asserts that the laws can be stated so as to be the same in form for all; no privilege is allowed.

But relativistic observers, those rather strange creatures who go about with clocks and measuring rods making signals, are not supposed to alter what they observe. The quantum observer does. Or more precisely, the circumstances that attend observation, for example the light that is required, alter what is observed and in a manner which cannot be determined even after the observation has been made. In consequence the knowledge that can be acquired is limited, because each observation upsets something else one would like to know. This was the first real hint that there are definite limits to scientific knowledge, limits not dependent on human patience or ingenuity. The argument depends, as all physicists know, on the finite size of Planck's quantum of action, but a very similar conclusion might have been reached before the quantum theory was thought of.

I think it is curious that physics remained deterministic in philosophy so long as it did. The power of accurate prediction in all systems diminishes with time. Even for the planets, those most orderly of creatures, a "Nautical Almanack" drawn up for the year 10,000 would be appreciably less accurate than one for next year. When one is interested in individual atoms this loss of accuracy can be enormous and catastrophic. Quite apart from any quantum considerations, even if one knew the positions and velocity of every molecule of a small sample of gas at one instant, one could not predict the path of a special molecule distinguished, for example, by being radioactive; one could not find, let us say, where it would first hit a wall of the vessel holding the gas. Even supposing every gaseous collision fully determinate, a small error in an original measurement mounts up, as Max Born has pointed out, with enormous speed. In a small fraction of a second all the detailed information is useless, and one can only treat the motion as one of diffusion to which only a probability answer is possible. So when time is taken into account one gets much the same result even if Planck's constant were many orders of magnitude less than it is. This kind of virtual indeterminacy is inherent in Maxwell's kinetic theory. It sets as real a limit to certain kinds of human knowledge, even given any thinkable extension of human skill, as does the quantum theory. The circumstances to which it applies are almost certainly of more human importance. The further ahead a prediction is made the less certain it becomes, and beyond a certain rough limit all that can be affirmed is a probability, often over a wide range of possibilities. It is an interesting question, for example, what is the best that could ever possibly be done in the long-range forecasting of weather. Can, say, a prediction of the weather on a particular day ten years hence ever have any validity?

Yet in some respects atoms behave in a surprisingly straightforward way. They pile together almost like spheres, like tennis balls in fact. They are slightly compressible and their distances depend a bit on chemical relationship; but one can place them in order in molecules and still more definitely in crystals. The work which is being done by the group at Cambridge under Perutz and Kendrew is a striking example of this. They have located most of the 10,000 atoms in the vastly complicated molecule of hæmoglobin, the first protein for which this has been done.

Single rows of atoms, and occasionally individual atoms, can actually be seen in the electron microscope. They seem as real, and almost as commonplace, as grains of sand.

In contrast to this matter-of-fact behaviour of atoms, the electrons are strange fairy-like creatures. They have no particular place; even when part of an atom, one can at best assign them a region in which they are most likely to be found. Unless they have an unusual amount of energy they cannot be assigned a definite path. Even their approximate behaviour is queer and to treat them properly requires highly abstract mathematics.

They can be created out of the energy of radiation but only in pairs with positive and negative charges, and the positive one soon dies in a suicide pact with another negative. In the same way, protons and antiprotons can be created and disappear. Certainly other kinds of elementary particles also have their anti-particles.

I should like to conclude by referring to two ideas of a somewhat more speculative character which may prove of importance in general thought.

The first is the relation between mass, energy and matter. In conventional mechanics, mass is the primary property of matter, even more so perhaps than extension since it is more constant. Now, as is well known, the theory of relativity made it probable that mass is energy considered from another point of view. This is expressed by Einstein's famous equation $E = mc^2$. Thus if energy is added to, or taken from, an otherwise closed system, the mass of the system will increase or decrease, as the case may be, though it takes a lot of energy to make much difference to the mass. Einstein's conclusion has been abundantly confirmed by the discovery of nuclear energy and other experiments in nuclear physics. Further, as I have just said, energy can be transformed into pairs of particles of opposite sign. It began to look as if matter is just another name for energy.

It may seem paradoxical to equate energy with the property, mass, that measures inertia, but remember that in Newtonian mechanics the bullet penetrates because of its inertia, which makes it continue in its state of motion. However, mass is only one property of matter, and perhaps not even the most important. There are indications, rather slight perhaps, but not to be ignored, that matter is *not* just another name for energy. The study of the many curious particles which have been found in cosmic rays and later produced in the giant so-called 'atom-smashers' has shown the persistence of certain features in spite of the bewildering number of spontaneous changes which these particles undergo. Two groups of these particles have appeared such that the net number in each group remains always the same, and this in contrast to a third group for which there is no such constancy. By the phrase 'net number' is meant the difference, in each case, between the numbers of the 'ordinary' particles and of the anti-particles. Thus electrons are members of one group called 'leptons', to which neutrinos also belong. In reckoning the net number of electrons, one subtracts the number of positrons from the number of ordinary electrons. Thus the creation of an electron-positron pair does not alter the net number. The rule states that no interaction between particles of any kind, including the photons of radiant energy and the mesons of the cosmic rays, can alter the *sum* of the *net numbers* of the three kinds of particles, electrons, neutrinos and μ mesons, which count as leptons. A similar rule holds for the class of particles, protons, neutrons, and some others, which rank as 'baryons'. Leptons can never change into baryons or reversely.

This seems a hint that underlying matter are two classes of entity, each of which indeed can appear in several different forms associated with various amounts of mass, sometimes electrically charged and sometimes not, but yet fundamentally the same. Matter is, I think, more than merely mass or energy. A neutrino has zero rest mass but yet is an entity. A piece of ordinary matter is made up of leptons and baryons in fixed numbers.

The mass of an atom at rest is a form of energy, but matter may be something extra.

This leads to one more instance, my last, of broad ideas derived from physics. It is one of the strangest facts of Nature that she is so fond of whole numbers. The mere existence of large classes of individuals identical in each class such as electrons, protons, atoms of fluorine, molecules of ethyl alcohol and many more is surprising enough. One might expect a continuous gradation of sizes, weights and charges. But it is not so. On the smallest scale only certain types of particles exist. The next most complicated things, atoms, are built of integral numbers of electrons, protons and neutrons. The numbers are fundamental and characteristic. An atom of carbon is a pattern based on the number six, there are six electrons, six protons and six, seven, or eight neutrons according to which of the three kinds of carbon atom it happens to be.

This is such a commonplace of science that one is apt to take it for granted. But surely this, and similar facts about other atoms, are most startling if one thinks. Further, the details of the pattern made by the electrons depend on another set of small integers, the quantum numbers. We cannot say yet whether this is also true of the arrangement of protons and neutrons in the nucleus, but there are indications that it may be. We are getting back to one of the earliest scientific ideas. Pythagoras taught that whole numbers are supreme.

It is worth notice that the masses of the atoms, even reckoned at rest and in the lowest energy state, show only rough regularities. The energy of formation and the mass representing it are variable, and though energy is sometimes divided into units, there is here a continuous variation, for the unit is $h\nu$ and ν can have any value. Yet even here we have units in a sense, and all photons of the same frequency have the same energy.

Molecules, again, are composed each of an integral number of atoms. It is true that at the moment of a reaction it may be difficult to say which atoms belong to a molecule or even if the concept of molecule is valid; but few would deny its importance in general. It is a concept which, though it owes something to the desire of the human mind to simplify, yet arises almost inevitably from Nature. If the Martians are competent chemists they will, sometimes at least, think in terms of molecules.

Rather the same can be said of the concept of a cell. Living matter is generally speaking cellular, and the cells that compose a given kind of tissue are mostly pretty much alike in size and shape. Even the organisms that they form tend, at least, to fall into species each containing very many similar individuals. In many cases also the component parts of an individual are multiplied, for example, scales or leaves.

While the 'atomicity' of electrons is perfect in the sense that each is in principle indistinguishable from any other, and the possibility of exchange without resulting difference is built into the theory, the atomicity of members of a species, of cells, and even of molecules is less rigid; but concepts embodying it are highly useful and represent something real in the world.

At present one can only speculate as to how far the complete atomicity of the elementary particle causes the partial atomicity one sees in biology, or for that matter in astronomy. If it is not a sufficient explanation, then we must look even deeper than the elementary particles for this principle of atomicity, which would make it very fundamental indeed.

I have tried here in a very discursive fashion to remind you of a few of the ways in which science has provided, and is providing, new ideas tied closely to experience, though often experience of a special character. These ideas constitute an achievement of which man may well be proud. It is surely something for beings, so utterly insignificant compared with the smallest of the stars that are scattered with reckless abandonment in the heavens, to be able to understand some at least of the principles which control their existence and enable us to perceive them.

To see these principles as applying equally on Earth, as manifest in the most varied phenomena; in the motions of the tides, in the blue of the sky, in the lightning flash, and in the falling apple; to prove our understanding by creating, on however small a scale, compositions of our own which use these principles in new ways of our own devising; to be beginning to see some light on the nature of living matter and how living forms can transmit themselves to descendants; all these are worth while and worthy to rank with the achievement of sculpture, of music or of literature.

Science is not merely the control but also the understanding of Nature. Its two aspects must be held in equal honour.

SUMMARIES OF ADDRESSES OF PRESIDENTS OF SECTIONS

STELLAR MOTIONS

STELLAR motions relative to the Sun are resolved into tangential and radial components. The former appear as proper motions and are seen as displacements of the direction in which the stars are seen. These proper motions, as Dr. R. v. d. R. Woolley in his presidential address to Section A (Mathematics and Physics) points out, are measured by comparisons between new and old catalogues of star positions determined by meridian instruments, and by comparison of new and old photographic plates. They can only be converted into linear velocities in km. per sec. if the star's distance is known. The radial component of a star's motion is directly observed in km. per sec. through the Doppler shifts in the star's spectral lines. Only in the case of the nearest stars can the distance be measured by the direct trigonometric method. In the case of a moving star cluster such as the Hyades, an independent method exists, as the observations of proper motion and radial velocity are consistent within the errors of measurement with the hypothesis that the motion of the cluster stars is equal and parallel. The geometry of this motion permits a determination of each star's distance. Recent measures conducted at the Royal Greenwich Observatory indicate that the dispersion in the velocities of these cluster stars is less than 0·5 km./sec., the total motion relative to the Sun being about 44 km./sec. The permanence of this motion raises interesting questions.

When the velocities of the nearby stars are resolved into three components along rectangular axes, pointing towards the centre of the Galaxy, the pole of the galactic plane and a third axis (tangential to galactic rotation), it is found that the distribution of velocities in each co-ordinate is more or less Gaussian and inferences may be drawn from the three velocity dispersions, which are unequal. Relaxation of the stellar velocities is incomplete. Discussion of the motion perpendicular to the galactic plane leads to a determination of the average density (due to stars, dust and gas) in the solar neighbourhood.
